Attempts to produce evidence of necrotizing properties by intracutaneous inoculation resulted in very minor or negative reactions. A suspension of organisms washed from a blood agar slant incubated fourteen days was matched with a 0.25 per cent typhoid bacillus antigen. The culture used originated from pulmonary abscess material seven weeks previously. Two series of three animals each of rabbits, guinea pigs, rats, and mice were used. Saline washings from blood agar slants were used as controls. The inoculum was 0.1 c.c. Consistent observation revealed several slight nodules or slight inflammation, but even these were insignificantly more marked than control reactions.

Attempts to induce invasion by intraperitoneal injection were performed with cultures from five to eight days old. Two series of 12 animals each, as in intracutaneous experiments, were used. Both blood agar and brain ascitic fluid broth cultures were used, with heavy inoculations (rabbits 5 and 10 c.c.; guinea pigs 3 and 5 c.c.; rats 3 c.c.; mice 1 c.c.) of standard suspension. Emulsions heated at 60° C. for two hours were used as controls. Observation was carried up to forty days. There appeared to be no evidence of

any kind, symptomatic, pathologic, or bacteriologic, of localization and multiplication of the organism. Since one series was carried through with densely pigmented growth and the other (broth culture) with no evidence of pigment, this property did not seem to be a factor in pathogenicity.

Intravenous inoculation of rabbits with large doses of both young and old cultures, variously made up, resulted in no abnormal temperatures or loss of weight, and the animals were continued with large repeated doses to develop an antiserum without apparent effect on their health. After final bleeding, autopsy revealed no significant changes, and cultures from the knee joint, the shoulder joint, right and left lobes of the lungs, liver, and spleen remained negative.

Attempts were made to introduce the organism directly into pulmonary tissue. Suspensions of young cultures were used, matched to both 1 and 2 per cent typhoid antigen. Quantities of 0.1 c.c. (rabbit), 0.08 c.c. (guinea pig), and 0.04 c.c. (mouse) were used in each series. The animals gained in weight and showed no abnormal temperatures during a month of observation. Autopsy revealed normal organs and negative cultures.

Intracerebral inoculations were given two series of animals, three guinea pigs and seven mice in the first, and four guinea pigs and two mice in the second. The animals were young, and several strains of young cultures were tried. Although maximum doses were used, there was no sign of any reaction whatever in any animal during a twenty-one-day period of observation. One mouse sacrificed in forty-eight hours yielded negative brain cultures.

SUMMARY

B. melaninogenicum appears to be common as a commensal and on surfaces normally or pathologically having a mixed flora. Detailed study suggests that this organism conforms to single type and is not one of a group of biochemically, morphologically, or serologically different types. All attempts, however, to show that it had any significance as a primary or secondary invader in mixed infections gave negative results, so far as clinical evidence or attempts in experimental animal infection could be correlated.

THE TREATMENT OF RHEUMATIC CARDITIS WITH AQUEOUS EXTRACTS OF STREPTOCOCCI*

JAMES C. SMALL, PHILADELPHIA, PA.

RHEUMATIC fever has received a great deal of attention during the past decade but the problems of its specific etiology, prophylaxis, and treatment have scarcely advanced beyond the stage of hypothesis. This serves to establish special interest in the disease aside from that engendered by the vastness of its humanitarian, social, and industrial aspects. One theory regarding its specific etiology is, that streptococci are in some manner concerned as the causative agents. Concerning the manner in which they act, and the strain or strains which are responsible, there is a wide divergence of opinion.

This discussion of the treatment of rheumatic carditis will be limited to the use of aqueous extracts of streptococci administered by injection after the manner of vaccines. It will introduce a relatively new system of dosage of bacterial products which has been developed during the past six years by means of applying aqueous extracts of streptococci in the treatment of patients suffering from chronic atrophic arthritis.

The relationship between rheumatic fever and atrophic or rheumatoid arthritis is aside from this discussion. All that concerns it is, that both groups of patients present at least one feature in common. This is a marked reactivity, or hypersensitiveness to streptococci, or to their derivatives administered parenterally. This character has been designated "hyperergy" by Swift.¹ It is an outstanding feature of the "rheumatic state." Many types of streptococci have been used in demonstrating the existence of this hypersensitiveness, so that the type of streptococcus used in studying the reactions arising in patients appears to be less important than does the fact that it characterizes patients both with rheumatic fever and with rheumatoid arthritis.

The reactions excited in arthritis by the injection of extracts of streptococci² furnish an almost ideal means of studying the degree of this hypersensitiveness. An outstanding feature of the reactions in arthritis is an activation of lesions in the joints which are so superficially distributed as to permit direct observation of objective symptoms. Trial dosage if it produces a severe reaction does not endanger life even though it may increase considerably the patient's discomfort. On the other hand the patient with rheumatic fever presents reactions in the heart as well as in the joints, and for this reason cannot safely be treated with overdosage. After dosage and certain principles in the treatment of the hypersensitiveness of atrophic arthritis had been established, it was a relatively simple matter to apply them in the treatment of similar hypersensitiveness characterizing rheumatic carditis.

*Received for publication, April 15, 1933.

DOSAGE OF THE EXTRACTS OF STREPTOCOCCI

The degree of this hypersensitiveness of the "rheumatic state" was determined by responses of patients with atropic arthritis to minute doses of aqueous extracts of streptococci. Throughout this study a saline extract of streptococcus cardioarthritidis was used under the designation of a soluble antigen.*

This product is prepared by suspending the streptococci in normal saline as in a vaccine. The concentration is relatively weak, being 100 millions per cubic centimeter. After seven days in a refrigerator, the bacteria are removed by filtration. The water clear menstruum containing the extractives is the undiluted soluble antigen. A series of sixteen dilutions of this are made, each successive one being one-tenth the strength of the last. The dilutions are conveniently designated as follows: 10^{-1} ; 10^{-2} ; 10^{-3} and so on up to 10^{-16} . A series of twelve dilutions only, beginning with 10^{-5} , and ending with 10^{-16} is used in treatment of arthritis, but only the last three, namely, 10^{-14} ; 10^{-15} ; and 10^{-16} are suggested in rheumatic carditis.

CHARACTERS OF THE REACTIONS

The reactions excited in this form of therapy are nothing more than aggravations of existing symptoms. They do not introduce new symptoms such as chills, high temperatures, etc., as are common in foreign protein therapy and which appear less frequently with the customary large doses of vaccines. They are triphasic but the triphasic character is brought out only by moderate overdosage. These three phases have been designated² "primary reaction," "period of euphoria" and "secondary reaction." They have also been observed by Crowe³ in his work with small doses of vaccine. He calls them "reaction," "response," and "relapse."

Proper dosage for the patient is followed by a period of euphoria beginning immediately upon the absorption of the antigen and lasting for a variable period of days (Chart 1). The outstanding features of this are relief of pain, buoyancy of spirits, and general stimulation. The euphoria terminates in the secondary reaction or "relapse," as Warren Crowe has more aptly named it. Administration of another suitable dose during the secondary reaction promptly terminates it by instituting another period of euphoria.

The primary reaction with moderate overdosage appears within the first twenty-four to forty-eight hours. It is usually followed by a period of euphoria which in turn terminates in the secondary reaction. It is a curious fact that further increases up to what may be termed gross overdosage do not proportionately increase the severity of the symptoms but rather tend to produce less stormy primary reactions which are delayed in their onset and prolonged in their course. These are referred to as "delayed primary reactions." They are not followed by periods of euphoria.

The delayed primary reaction begins forty-eight hours or more after an injection. During this interval no change is noted in the patient's clinical

*The soluble antigen used in this study has been supplied through the courtesy of Sharpe and Dohme, Philadelphia, Pa.

condition. It comes on gradually with symptoms which are of a general character rather than focal; e.g., malaise, lassitude, and generalized aching. It tends to be prolonged. Administration of another injection maintains the symptoms.

Chart 1.—In this diagrammatic chart the average level of the patient's symptoms is indicated by the solid lines at levels 1 u, 10 u, 100 u and 1000 u. The swing of the symptoms above or below this level is represented by the hatched lines. Suitable, or unit dosage of the extractives of streptococci is indicated at 1 u, and excessive dosages at 10 u, 100 u and 1000 u. The different reaction phases and their relations to the time of injection are illustrated.

Chart 2.—At levels A and B are represented the zones of reaction of different patients following injections of the extractives of streptococci. At levels A' and B' the shifting of these zones to ranges of stronger dilutions is shown.

The secondary reaction follows a period of euphoria, usually of more than forty-eight hours' duration, during which there had been a well-marked improvement in the patient's clinical condition. It comes on abruptly with symptoms which are largely focal in type; e.g., increased pain, swelling, and red-

ness about the involved joints. It is terminated promptly by repeating the injection of the antigen.

ZONAL CHARACTER REACTIONS

The reactions are limited to a certain definite range of dosage. The administration of amounts below or above this range is not followed by reactions. This range varies for different individuals, and it shifts to stronger dilutions as treatment is continued in a given patient (Chart 2). This zonal character of the reactions is a very unusual phenomenon. Its recognition has great practical importance in adjusting dosage as will appear later under the discussion of the principles in the applications of treatment.

DISCUSSION

The extreme dilution of these extracts at first appears to be an absurdity. Experience over the period of years, during which repeated checks with blank solutions carrying only the saline and the traces of preservative used in extracts, have shown that contact with the streptococci imparts something not present in the blanks, which is potent in inducing reactions in arthritis even in these dilutions. The dilutions were arrived at gradually through trials of them in arthritis proceeding from the stronger ones down through the weaker ones. The guiding purpose was that of obtaining dilutions so weak that when convenient amounts were administered to patients with arthritis, no activation of the joints would follow. Encouragement was had from the fact that as the reactions were avoided, clinical improvement became more constant and more pronounced.

Another advantage of these minute dosages developed as the work progressed. They appear to act in the direction of desensitization only, perhaps because they are too small to increase the patient's reactivity. There is no need therefore to resort to intravenous injection as a precaution against this. This is a decided advantage over vaccines which even in small doses are prone when injected subcutaneously to reverse the process thereby increasing the patient's reactivity.

These doses are smaller than any yet used in biologic therapy. The nearest approach to them are those of tuberculin therapy. Others have used small doses of vaccines of streptococci in treatment of arthritis, but they can scarcely be compared with the ones used in this work. Warren Crowe,³ who has been using polyvalent vaccines of streptococci in arthritis for some twenty years, has arrived at a minimal dosage of 100 (only) microorganisms, and seldom goes above a dosage of 10 millions. Burbank⁴ states that some patients require initial doses of 50 (only) bacteria of polyvalent streptococcus vaccines. Each of these workers as experience was gained, has been reducing dosage.

PRINCIPLES IN THE APPLICATION OF THIS THERAPY

In contrast with treatment of foreign protein "shock" therapy, reactions must be avoided in this therapy if results are to be obtained. At all times to

avoid doses which are followed by reactions becomes the first principle of treatment. Since dosage may be above as well as below that range in which reactions occur, this principle must be further qualified by stating that dosage must be *below* that followed by reactions. This can be determined only by trial in the individual case, beginning with the weakest dilutions and gradually increasing dosage until a mild reaction appears. Thereafter dosage should be decreased slightly for best results. The continued use of doses within the zone of reactions aggravates the patient's symptoms. Persistent dosage above this zone, within certain limits, appears to influence the disease very little one way or the other.

The second principle is, that dosage to be most effective should be followed by periods of euphoria. It is not sufficient to avoid reactions but improvement must be obtained upon the absorption of the material injected. The optimum dosage is that amount which is followed by the longest period of euphoria. An amount which is followed by a period of euphoria lasting more than five days is regarded as satisfactory early in a course of treatment. If the euphoric periods are shorter than five days the dosage should be increased fractionally. The periods of euphoria tend to grow shorter under constant dosage during a course of treatment. When this occurs, it constitutes an indication for increasing dosage.

A third principle may be stated. Increase dosage only when the repetition of fixed amounts is followed by a shortening of the periods of euphoria. The periods of euphoria terminate in the secondary reaction. The appearance of this latter indicates that more antigen must be administered since the benefits derived from the last injection are at an end. Later in the course of treatment, as dosage is gradually built up the periods of euphoria lengthen, and secondary reactions grow milder. Finally the secondary reactions fail to appear as the arthritic process becomes quiescent.

The chief difficulty arising in practice is that of differentiating the delayed primary reaction of gross overdosage from the secondary or "relapse" reaction which calls for a repetition of the dose. One must rely on the symptoms presented in attempting to differentiate between the two reactions. If uncertain, the course of events following a repetition of the dosage usually suffices to clear up the doubt. Relief follows the repetition of dosage in the case of a secondary reaction and fails to do so in case of the delayed primary reaction.

PRESENTATION OF SELECTED CASES OF RHEUMATIC CARDITIS

With this information fairly well correlated and upon a background of experience in favorably influencing the "rheumatic state" as evidenced in arthritis, the problem of influencing in a similar manner the "rheumatic state" as seen in rheumatic fever has been approached by practically identical methods of practice. To present this work, a small group of 13 patients has been selected. These were chosen not because they demonstrate the most favorable results with this therapy but rather to illustrate certain errors which were made because of premature attempts to apply the method in rheumatic

conditions during the course of its development in arthritis. Thereby the parallelism between its applications in the two conditions can best be demonstrated. More recently all except one of these have received the benefits of dosage more properly adjusted to their needs. The observations on ten of them have extended over periods ranging from two to more than five years. The remaining three have been observed for less than a year, and serve to illustrate the results with the present methods. In three patients acute exacerbations followed injections of the larger doses which were employed from two and a half to four years ago. These followed an injection closely enough to suggest that they represented the primary type of reaction. Acute exacerbations have not occurred with dilutions of the soluble antigen weaker than 10^{-11} . They have also been absent as a spontaneous occurrence in patients treated by the weaker dilutions during the past two and a half years. In Table I are presented the summary of the outstanding clinical manifestations, the range of dosage used, and the results in each of the thirteen patients. Four (J. G., R. H., J. J., and T. K.) were seen first in acute attacks of rheumatic fever, or chorea, and treatment with the soluble antigen of streptococcus cardioarthritidis was begun with the passing of the acute symptoms. Six (E. H., K. N., S. W., W. R., A. L., and J. B.) were seen first during convalescence from a febrile attack of rheumatic fever or chorea. Three (R. McC., M. C., and M. L.) presented long-standing rheumatic disease of the heart, which was still active. Two of these had had no acute attacks of rheumatic fever or chorea. The other had two attacks of chorea and three of rheumatic fever. Only two patients were seen in their initial attack of rheumatic fever. The others, with the exceptions mentioned above, had had multiple attacks of rheumatic fever, or chorea. Eight of the patients were children with ages ranging from three years to thirteen. Three patients had active chorea when first seen, two had subcutaneous nodules, and another had a history of them with a previous attack of rheumatic fever. Three had pericarditis. One had acute iritis accompanying rheumatic fever with pancarditis. All had valvular cardiac lesions.

The range of dosage of the soluble antigen of streptococcus cardioarthritidis is charted opposite each patient's record in Table I. It will be seen that in the earlier applications of this antigen the doses were larger and that later ones were smaller. Three patients developed acute exacerbations and four others exhibited mild reactions to individual injections. All of these were among the earlier cases and all with the larger doses employed at the time. One of these patients died of cardiac failure in an acute exacerbation of pancarditis, the remaining six patients responded favorably when doses were reduced below the zone of reactions and have remained quiescent since.

The case (J. G.) is of interest because only mild reactions followed large individual doses, and the acute exacerbation occurred while dosage was being reduced. It represents an instance of tolerance to large doses and the entering of the zone of reaction from above. The other instances of acute exacerbations and of mild reactions to individual doses occurred while dosage was being increased. They are examples of entering the zone of reaction from below.

TABLE I. THE RANGE OF DOSAGES USED IN THE TREATMENT OF EACH PATIENT IS CHARTED

The range of dosages to which no reactions occurred is indicated by straight lines. The wavy lines show the range of dosages to which mild reactions occurred. Acute exacerbations are indicated by the hatched lines.

KEY OF SYMBOLS:—

— ZONE OF NO REACTIONS.

~~~~~ ZONE OF MILD REACTIONS.

||||| ACUTE EXACERBATIONS.

Patient J. J. is also worthy of special note since she was treated by repeated courses of injections of dilutions  $10^{-8}$  and  $10^{-9}$  during a period of two years without noteworthy effect on a persistent chorea of low grade. When dosage was dropped to the  $10^{-10}$  and  $10^{-15}$  range, the choreic symptoms disappeared and improvement in the general condition became evident after a few weeks.

In order to present more in detail the methods of this treatment Tables II and III are included.

In Table II are tabulated the dosage, intervals between treatments, certain clinical and laboratory data in the case of K. N. who showed a relapse under treatment when dosages were being increased rapidly. While a gain in body weight and a decrease in pulse rate occurred from the first, a definite tendency to quiescence of the rheumatic carditis did not appear until the

## SMALL: RHEUMATIC CARDITIS

dosage was dropped from  $10^{-12}$  dilution to  $10^{-14}$  dilution. Amounts of 0.05 c.c. to 0.1 c.c. of the latter were, in the light of further experience, still too large so that not until after treatment had been carried out for about five months was progress regarded as satisfactory. Apparently by this time a tolerance to a dosage of 0.1 c.c. of dilution  $10^{-14}$  had been established. This long pre-

liminary period is not observed in cases where treatment is begun with a much smaller dosage. This is illustrated in the record of patient W. R. as presented in Table III.

It is desired to call attention to the intervals between treatments as employed in these patients. Treatment is begun at seven-day intervals. After a course of seven or more injections, intervals of ten days are employed. Later fourteen, twenty-one, and twenty-eight days are allowed to elapse between treatments.

The treatments at monthly intervals are continued for at least a year after the carditis appears quiescent by all criteria used in estimating its activity. This is a precaution against relapse in a disease of the persistent character amply demonstrated for rheumatic carditis. When treatment is stopped, it is discontinued preferably during the summer months or at a season of lowest prevalence of the acute manifestations of rheumatic fever. In addition to the clinical observations used in estimating quiescence or ac-

tivity of rheumatic carditis, laboratory determinations of the hemoglobin, of erythrocytes and leucocytes, and of sedimentation distance of erythrocytes are used in following the course of the disease. Since the extract employed has been prepared from a single strain of streptococcus cardioarthritidis, the opsonic index readings of the patient's serum against this strain have been found to be most helpful in the matter of regulating dosage. Overdosage is regularly reflected in its depression of the opsonic index.

#### PRACTICAL APPLICATION IN RHEUMATIC CARDITIS

The treatment of rheumatic carditis with the aqueous extract of streptococcus cardioarthritidis as developed may be briefly outlined. An initial dosage of 0.05 c.c. of dilution  $10^{-16}$  of the soluble antigen is injected subcutaneously. The injections are repeated at intervals of from five to seven days, using 0.05 c.c. each for the first three injections. If tachycardia, cardiac arrhythmia or mild rheumatic pains develop within the first forty-eight hours the amount must not be increased until these symptoms fail to appear following an injection. Therefore limit any increase of dosage to 50 per cent, or less of the amount last administered. The most favorable results are obtained when the dosage is adjusted so as to avoid reactions. Improvement manifests itself in the erythrocyte count, leucocyte count, the hemoglobin, the sedimentation distance of erythrocytes, and the opsonic index of the patient's serum against streptococcus cardioarthritidis after from four to six treatments. No improvement usually indicates too large a dosage of the antigen.

Evidence of continued improvement after six or eight treatments at intervals of from five to seven days should be followed by treatments at intervals of from ten to fourteen days. Later the intervals may be lengthened to three or four weeks. Treatments at monthly intervals should be continued for at least a year after all signs of activity have disappeared. Dosage begun at 0.05 c.c. of dilution  $10^{-16}$  is usually not carried above 0.1 c.c. of dilution  $10^{-14}$ . Dilutions stronger than  $10^{-14}$  are not regarded as necessary and are not recommended in rheumatic carditis.

#### SUMMARY

There is a range of dosage of the aqueous extracts of streptococcus cardioarthritidis in which dangerous exacerbations of rheumatic fever occur.

In the patients observed to date such exacerbations have not occurred with a range of dilutions weaker than that designated dilution  $10^{-11}$  streptococcus cardioarthritidis soluble antigen, and mild reactions to individual doses occur infrequently in the range of dilutions weaker than dilution  $10^{-13}$ .

When dosages have been kept below those amounts followed by mild reactions to the individual injections clinical improvement has occurred regularly.

Dilutions  $10^{-16}$ ,  $10^{-15}$ , and  $10^{-14}$  only are recommended in the treatment of rheumatic carditis.

## THE LIGHT FILTERING INDEX OF BLOOD SERUM\*

---

### A DISCUSSION OF ITS CLINICAL APPLICATION

---

G. L. ROHDENBURG, M.D., AND R. SCHLEUSSNER, M.D., NEW YORK, N. Y.

---

IN A PREVIOUS paper,<sup>1</sup> it was suggested that the power of human blood serum to filter out light might possibly be utilized as a prognostic aid. The present paper records a technic which renders this suggestion practical, and presents a discussion of the procedure as applied to medical conditions.

Inasmuch as both the method of examination and the theoretical basis upon which the procedure under discussion is founded are somewhat novel, it seems advisable to consider certain aspects of the matter in detail. We have to deal with two factors: (a) serum and (b) light. Viewed from the purely physical standpoint, serum is a colloidal system. If one be permitted to revert to an elementary presentation, a colloidal system may be said to be composed of particles which may, or may not, vary in size, and which are separated from one another by varying amounts of a substance of different physical characteristics than the aforementioned particles, this separating substance being termed interface. Picturing such an arrangement one may conceive that a light wave passing through the serum encounters the colloidal particles, and that these either block, absorb, or reflect the light, thus acting as a filter. The amount of light which is held back would vary according to the conditions within the colloid system, and these conditions are dependent upon the size of the particles, the amount and nature of the interface, and the arrangement of particles and interface.

The current concept of light is that it is energy in the form of a wave and that the color of the light is related to, or dependent upon, the length of the wave. The unit by which the length of the light wave is measured is the Ångström's unit which is one ten-millionth of a millimeter.

\*From the Achells Laboratory, Lenox Hill Hospital.

Received for publication, May 12, 1933.

Under a grant from the Fred Weingarten Fund.

It has been found by actual observation (1) that light of different wave lengths, when passed through a layer of serum of definite thickness, the intensity of the light being relatively constant, is held back in varying degrees. It is upon this observation that the method of examination is based.

The Pulfrich photometer equipped with two filters having as their center of light filtration the following wave lengths (plus or minus 100 Å units) is employed, 7,200 Å and 4,300 Å. The mechanism and operation of this instrument has been described<sup>1</sup> previously. A standardized cell having a depth (thickness of serum layer) of 2.5 mm. is used and this cell is so constructed that the width of the serum layer is 3 mm. The portions of the cell which are not actually the walls of the cell cavity itself are painted black to cut out extraneous light. Blood for examination is collected in a Wright capsule after finger puncture. To give a sufficient amount of serum the body of the capsule should be 3.5 cm. in length and the bore approximately 8 mm. Blood can also be obtained by venepuncture, but this method is not necessary. Hemolyzed sera should be discarded. The time of taking the specimen is not material, if not too soon after eating, provided that in any given instance it is taken at the same time in all subsequent examinations; for example, if the first determination is made on a specimen collected before breakfast or two hours after breakfast, then subsequent specimens should be collected at the same relative time of day. After the serum is separated from the clot it may be examined at any time within twelve hours.

The standardized cells of the photometer are filled, one with distilled water, the other with the serum to be examined. In the manner described in the booklet of instructions which accompanies the instrument, the amount of light which is passed by the serum with each of the specified filters is then determined. The reading obtained with the 4,300 Å filter is subtracted from that obtained with the 7,200 Å filter. The result thus obtained indicates the amount of light, of the band situated between the central points of the two chosen filters, which has been blocked out. This result is then divided by the number of 100 Å units present in the band; i.e., 29.

*Example.*—The reading with the 7,200 filter indicates the passage of 95 per cent of the light, while with the 4,300 filter, 40 per cent of the light is passed. Between these two filters then, 55 per cent of the available light has been lost (95 minus 40). Since in the band between 7,200 and 4,300 there are 2,900 units, 55 is divided by 29 giving a quotient of 1.89. The filtration index in this instance is 1.89, but since in the computations recorded in this paper the second decimal place is either advanced one if above 5 or discarded if below 5, the corrected index is 1.9.

Expressed concretely, the light filtration index is obtained by subtracting the amount of light passed by the filter with the shorter wave length from that passed by the filter with the longer wave length, and dividing the result by the number of 100 Å units in the band lying between the center points of the two filters.

Isolated determinations of the index are valueless both from the diagnostic and prognostic standpoint, a question which has been considered in

the first report. It is only if the index is determined daily, or at possibly slightly less frequent intervals, that the collected data become of value. In the present paper we shall consider the application of the light filtration index in a group of medical conditions, surgical conditions being considered in another paper by Dujat and Kahan. Based upon 129 single observations made on normal individuals, the light filtration index normally varies between 1 and 3.1 with an average of 2.1. The distribution of the varying indices over the range, as expressed in percentages of the group is shown graphically in Chart 1.

A series of six normal individuals were examined every other day for a period of fifteen days. The data of these cases is given in Table I. In Case 1 the index was constant over the entire period. In Case 2 the index was constant over the entire period, except for the seventh day, the drop of 0.1 being

Chart 1

associated with constipation. In Case 3 the minor variations were associated with menstruation. In Cases 4, 5, and 6 the changes in the index were associated with constipation.

TABLE I

| DAYS   | 1   | 3   | 5   | 7   | 9   | 11  | 13  | 15  | MAXIMUM VARIATION |
|--------|-----|-----|-----|-----|-----|-----|-----|-----|-------------------|
| Case 1 | 2.2 | 2.2 | 2.2 | 2.2 | 2.2 | 2.2 | 2.2 | 2.2 | 0.0               |
| Case 2 | 1.9 | 1.9 | 1.9 | 1.8 | 1.9 | 1.9 | 1.9 | 1.9 | 0.1               |
| Case 3 | 2.7 | 2.7 | 2.5 | 2.5 | 2.7 | 2.8 | 2.7 | 2.7 | 0.3               |
| Case 4 | 2.0 | 2.0 | 2.0 | 2.0 | 1.9 | 2.0 | 2.0 | 2.0 | 0.1               |
| Case 5 | 1.9 | 1.9 | 1.9 | 1.8 | 1.9 | 1.9 | 1.7 | 1.8 | 0.2               |
| Case 6 | 2.5 | 2.5 | 2.5 | 2.5 | 2.5 | 2.5 | 2.5 | 2.4 | 0.1               |

*Examples of the Behavior of the Index in Disease.*—In a case of chronic nephritis (No. 3297, Chart 2) there was a marked nitrogen retention. On admission to the hospital the index was 1.4 at which time the patient was on a low nitrogen diet. He was then placed on a diet consisting solely of fruit juices, and within three days his index rose to 2.8 and promptly fell within twenty-four hours when he was again placed on a low nitrogen diet. During this period there had been no change in either the clinical condition or the blood chemistry. In the second, Case 9477 the clinical diagnosis was chronic

nephritis, hypertension and cardiac decompensation. As is shown in Chart 2 there were variations in the index with a gradual tendency over the period of seventeen days to reach a higher level. During this period, however, there was no decisive change either for better or worse in the patient's condition.

Changes in the index of a much more marked character were also observed in a case of Banti's disease (Chart 3, Case 35433) during an observation period of nineteen days. The significance of these variations could not be determined since the clinical condition of the patient remained practically unchanged.

In a case of hyperthyroidism (Chart 4, Case 35506) rather marked variations of the index were also observed during the fifteen-day period of observation. There was a general tendency of the index to run to successively higher

Chart 2. — 3477. — 2297

Chart 2

Chart 3. — 35433

Chart 3

values. This rise in the index was associated with a clinical improvement in the patient.

A further identification of the various factors which may influence the filtration index is afforded in Case 35043, Chart 5. This patient was admitted to the hospital with a diagnosis of chronic cholecystitis with cholelithiasis. The first index taken gave a value of 1.2. Five days later the index was again determined on a specimen taken about two hours after the administration of the dye used to demonstrate the gallbladder roentgenographically, and the index was found to be 3.0. Four days later the index had fallen to 1.5. Four days after the third index was determined the patient was operated upon and the index determined on a specimen taken twelve hours postoperation. The index had fallen to 0.6. The index was again determined three and seven days postoperation and a rise first to 1.8 and then to 2.7 was

demonstrated. The significance and application of the fall in the index directly postoperative and the subsequent rise is discussed in the subsequent paper by Drs. Dujat and Kahan.

Chart 4

Chart 5

The influence of parenteral injection of foreign protein is shown in Case 35445, Chart 6. This patient was admitted to the hospital with a diagnosis of subacute arthritis of undetermined etiology. Vaccine therapy was given on the dates indicated. The termination of the vaccine therapy was followed by a sharp drop in the index.

Chart 6

Chart 7

Suggestive of the use of the index in diagnostic differentiation is the curve in the Cases 33401 and 33425. Both of these patients were admitted to the hospital with a history of generalized pains, sore throat and fever.

Still another example is shown in Case 35531 (Chart 8). This patient with lobar pneumonia was admitted to the hospital on October 29. The first index was taken November 3 and was 1.3. The first day of completely normal temperature was November 5 when the index was 0.8. The indices on November 7, 8, 9, 10, 11, 12, 14, 15, 16, and 17 were as follows: 1.8, 1.3, 1.9, 1.1, 2.1, 1.9, 2.5, 2.5, and 2.5.

Still another example is given in Chart 9, Case 34501, one of pneumonia in which the index dropped from 1.3 to 0.7 on the first day of normal temperature. The index does not apparently change markedly previous to a decided change in the patient's condition which occurs suddenly as is shown in Case 33096, Chart 9. This patient had a lobar pneumonia and had an index of 2.0 just a few hours before a fatal cardiac collapse. Another case of lobar pneumonia, Case 35554, Chart 9, shows another phase of reaction of the index.

Chart 9

Chart 10

This patient who was very gravely ill had an index varying between 0.7 and 0.9, while the temperature was dropping from 105° to 102.5° F. With the temperature still at 102.5° F., there occurred a rather sudden and very marked improvement in the patient's clinical condition and coincidental with this the index rose to 2.4, to drop forty-eight hours later to 1.3. From this point the index rose steadily to 2.1, the rise antedating the return of the temperature to normal.

In long lasting bacterial infections, in which from the onset it is known that the outlook is unfavorable, as in bacterial endocarditis, fluctuations in the index associated with variations in temperature are also observed. Thus in the patient in Case 35676 (Chart 10) one of bacterial endocarditis, admitted to the hospital November 15 and dying February 4, this was observed. The first index was taken on December 1, and between then and December 21 the index was repeatedly determined. The relation of the temperature curve,

and the curve of the index is graphically shown in Chart 10. In the patient in Case 35428, also bacterial endocarditis, admitted to the hospital October 19 near the termination of the condition, the first index on October 26, was 0.8 while two days later it was 0.5. On October 30, a transfusion was given and while this has in most other instances been followed by a sharp rise in the index, it was in this case followed by a further drop to 0.4. Twenty-four hours after the time of the last index the patient died.

### CONCLUSION

If light of differing wave lengths be passed through nonhemolyzed blood serum a definite absorption of the available light occurs. The rate at which the light is absorbed, when calculated for bands 100 Å units in width has been termed the "light filtration index."

In normal individuals this index remains fairly constant over periods as long as fifteen days, minor variations occurring in consequence of simple physiologic disturbances such as constipation, menstruation, etc. The normal index varies between 1.0 and 3.1 with an average of 2.1.

The index is affected by the parenteral injection of foreign proteins, by the ingestion of colloids such as dyes and probably by still other factors.

In pathologic conditions associated with fever the termination of the fever is characterized by a sharp drop in the index and convalescence by a steadily rising index.

An index steadily between 2.2 and 2.6 is of good prognostic import as is a steadily rising index. A consistently low index is of bad prognostic import.

The changes which have been observed in the study of the phenomenon thus far warrant an intensive study in specific disease groups of the behavior of this biophysical change in blood serum so that definite laws guiding in the interpretation of the results may be established.

# CHRONIC MYELOSIS IN CHILDREN\*

## WITH REPORT OF A CASE

A. A. EISENBERG, M.D., AND HARRY WALLERSTEIN, M.D.  
NEW YORK, N. Y.

BAAR and Stransky<sup>1</sup> in their well-known *Klinische Haematologie des Kindesalters*, state that "myelogenous leukemia is well known, but exceedingly rare." In the age table of Reprint No. 143 of the Cancer Commission of Harvard University, the base of the age curve does not touch the 1-9 year line. For this reason we feel justified in reporting an additional case of this disease, and in presenting, in tabulated form, all the cases previously reported in the literature.

### CASE HISTORY

The patient was a Jewish boy, nine years of age, admitted to Sydenham Hospital on June 5, 1929, with six months' history of gradually increasing weakness, loss of weight and progressive increase in the size of his abdomen. Aside from slight shortness of breath, induced apparently by his enlarging abdomen, there were no other symptoms. At the beginning of his complaint he was seen by an outside physician who ordered a blood count, with the following findings: Hemoglobin 35 per cent, erythrocytes 2,140,000, leucocytes 425,000, thrombocytes 520,000. The differential smear showed 41 per cent immature neutrophiles, 4 per cent mature neutrophiles, 3 per cent eosinophiles, 3 per cent basophiles, 33 per cent neutrophilic myelocytes, 4 per cent basophilic myelocytes, 10 per cent myeloblasts, 1 per cent monocytes, and 1 per cent lymphocytes.

Six weeks before his admission to this hospital the boy was admitted to Mt. Sinai Hospital, where he stayed two weeks. An abstract received by us of his history there showed a diagnosis of chronic myelogenous leucemia.

The boy's past history showed a normal full-term delivery, weighing 11 pounds, with normal development thereafter. He was breast fed for one year and then put on the regular house diet. His childhood diseases included measles, chickenpox, and whooping cough. The family history was irrelevant.

Physical examination showed a young boy with good physical development and fair nourishment. He was rather pale, giving the appearance of one who is chronically ill. There was a slight dyspnea and orthopnea. He did not cough, and there was no cyanosis. His temperature by rectum was 101.6° F., pulse 116 per minute, and respiration 24 per minute.

The positive findings included marked deviation, to the right of the nasal septum. His eyeballs were large and protruded from their sockets. There were no other eye signs. There was marked pulsation of the vessels on both sides of the neck, and in the suprasternal notch, where a systolic thrill could be palpated. The thyroid gland was not enlarged. The heart appeared to be pushed up somewhat, the apex beat being in the fourth interspace inside the midclavicular line. There was diffuse precordial pulsation and a soft systolic murmur all over the precordium. The lungs were normal.

Examination of the abdomen showed it to be enormously distended, and the superficial veins were enlarged. On palpation an enormously hypertrophied spleen was felt reaching

\*From the Department of Pathology, Sydenham Hospital.

down to the symphysis pubis and extending over to the right side. To percussion there was only a small area of resonance, just below the liver.

The lymph nodes in the cervical, axillary, epitrochlear, and inguinal regions were all palpable as small granular masses.

Examination of the eyegrounds showed typical leucemic fundi with blurred, hyperemic discs, and highly dilated, tortuous veins. The arterioles were also dilated but to a lesser degree. There were no hemorrhages or exudative spots.

During the patient's stay at the hospital his temperature varied between 97 and 102° F.

Urinalysis at all times showed a trace of albumin with no other findings. The basal metabolic rate was +10. Blood chemistry was normal. A blood count at that time showed 28 per cent hemoglobin, 1,520,000 erythrocytes, 336,000 leucocytes, and 484,000 thrombocytes. The differential leucocyte count showed 10 per cent mature neutrophils, 16 per cent immature or band neutrophils, 20 per cent metamyelocytes, 12 per cent neutrophilic myelocytes, 20 per cent basophilic myelocytes, and 22 per cent eosinophilic myelocytes. Numerous blood

Fig. 1.—Authors' case. Autopsy. Note size of spleen. Weight 5,223 grams.

counts done at different periods during the next two years always showed a similar picture except at one time when the total leucocyte count was brought down to 50,000.

During that time the boy was admitted to the hospital several times and also watched through the dispensary, receiving several courses of benzol treatment and also of deep x-ray therapy to the spleen and long bones.

He received, in all, six transfusions, when warranted by his progressing anemia. They varied in amount from 300 to 500 c.c. and were all given by the Unger method of direct transfusion. The boy was of the Group 1 of the Jansky classification, or the class of universal donors. At each successive transfusion the reaction seemed to be more severe, and when on May 13, 1931, he was given 400 c.c. of carefully cross-matched blood from a professional donor, his temperature rose to 104° F. with a very rapid pulse, chill and hemoglobinuria. He died rather unexpectedly eight hours after the transfusion and approximately two and one-half years after his disease was first diagnosed.

Autopsy performed on April 14, 1931, revealed a large spleen and liver, the former measuring 37 by 21 by 10 cm. and weighing 5,223 gm., while the latter measured 27 by 23 by 8 cm. and weighed 2,680 gm. (Fig. 1). On section of the spleen the cut surface was angry-

red in appearance, with large outstanding granules. Microscopically, there was myeloid metaplasia and infiltration of the spleen, liver, kidneys, lungs, lymph nodes, and bone marrow (Figs. 2 and 3).

*General Features of Chronic Myelosis in Children.*—Mention has been made of the rarity of this condition. It is interesting to note that, rare as it is, it is exceedingly frequent when compared with chronic lymphadenosis in children. There is but one genuine recorded case of the latter condition. By far the

Fig. 2.—Spleen. Note absence of malpighian corpuscles and normal splenic architecture. Typical myeloid metaplasia present. (Authors' case.)

Fig. 3.—Liver. Note sinusoidal infiltration with myeloid cells. This choice of site for infiltration is typical of myelosis as contrasted with the periportal infiltration in lymphadenosis. (Authors' case.)

greatest incidence of leucemia in children lies in the acute types with the acute myelogenous leucemia even more prevalent than the acute lymphatic. The literature includes only 32 cases of chronic leucemia in children. The differentiation, however, between acute and chronic leucemias is often difficult.

It has been repeatedly stressed that in children, even more than in adults, the clinical difference between acute and chronic leucemia, lies not only in the duration of the disease but (and principally so) in the fact emphasized by

Fraenkel<sup>11</sup> that acute leucemias begin with those symptoms with which chronic leucemias end. It must be added, however, that in children chronic myelosis often runs a course so much more rapid than in adults, that on the duration alone one would be tempted to regard it as an acute case, were it not for the absence of the classical symptoms of acute leucemia, namely, hemorrhagic diathesis and an ulcerated mouth. One thing, however, is of great theoretical interest; when a case of chronic myelosis in a child develops the above-mentioned hemorrhagic and mouth symptoms, although the downward progress becomes much more rapid than in a true acute case, the blood picture remains typical of chronic myelosis, even though the case is now an acute one clinically.

Whatever our conception of acute leucemia and its relationship to the chronic form may be, chronic myelosis is a definitely independent clinicopathologic entity. It is a hyperplasia of the myeloid (granulocytic) tissue of the bone marrow and a metaplasia of the myeloid tissue in all the organs where embryonal totipotent mesenchyme is present, myeloid metaplasia in the spleen, liver, and lymph nodes. Hematologically, it expresses itself qualitatively in the presence of immature myeloid cells (granulocytes) from the myeloblast to the metamyelocyte, and quantitatively, in a very high leucocyte count, from 50 to several hundred thousand cells per cubic millimeter. The latter, the very high count, is not an essential feature, since the disease may run its entire course as a subleukemic myelosis with 20 to 50,000 cells, or even as an aleukemic form, with 1 to 10,000 cells per cubic millimeter of blood.

As to the etiology of this extremely interesting condition, though many attractive theories have been proffered, none have been associated with definitely proved facts, and we still know nothing that even begins to approximate certainty. The many hypotheses include the infection theory, as championed by von Hansemann, Manta, Mosler, Fontana and others, the belief that it is a neoplastic process, as claimed by Ribbert,<sup>26</sup> Banti, Warthin, Mallory and Piney, the tuberculosis theory, and lastly the theories of Ziegler<sup>21</sup> and of Naegeli<sup>23</sup> who believe that the disease is a disturbance of tissue correlation and can be traced to disturbed endocrinal relationships.

For a time the most alluring hypothesis was that which regarded all chronic leucemias, the myeloses and lymphadenoses, as a neoplastic process. Piney,<sup>26</sup> however, sounded the keynote of this theory when he said, "it seems the neoplastic hypothesis presents the *fewest difficulties*." True, from the viewpoint of monophasic anaplasia, leucosis would be regarded as a neoplastic process, but there are too many objections from other points of view, for such a theory to be more than a pretty parallelism. Some of these objections are the absence of infiltrative qualities in the invaded tissues, lack of close relationship to trauma or chronic irritation, the work of Ellerman in transmitting fowl leucoses, remissions and exacerbations, the nature of the hyperplasia, which involves the entire tissue system, over a wide area, rather than an organ, and finally the occurrence of the so-called "leucemoid" blood picture, at times indistinguishable from a true leucemia, yet returning sooner or later to the normal. One also recalls numerous authentic observations of leucemia where the

blood picture would become normal under the influence of an intercurrent infection, and Jaffe<sup>13</sup> correctly stated that "these facts are difficult to reconcile with the conception that leucemia belongs to the malignant tumors." Finally, the tuberculosis theory is to be mentioned, only to be dismissed as being without any proof.

Despite the lack of positive evidence thereto, we still feel that the most possible progress toward discovering the etiology of this condition, will be made along the work of Ziegler and of Naegeli, on the basis that there is a disturbance in the endocrinal relationship with abnormality of the internal secreting organs.

## COMMENT

At the conclusion of the review of seemingly authentic cases, a few impressions appear justifiable. In the first place the mutual incidental relationship between chronic myelosis and lymphadenosis in children is the same, though markedly accentuated, as in adults, there being only one case of chronic lymphatic leucemia in children as against thirty-three of the myeloid type. Again, acute leucemias (which are much less common in adults than are the chronic forms) are, conversely, more frequent in children. So far as the aleucemic forms of leucemia are concerned, they are much more common, both in children and in adults, in myelosis.

In order of their frequency, therefore, the various forms of leucemia would appear as follows:

- CHILDREN
1. Acute myelosis
  2. Acute lymphadenosis
  3. Chronic myelosis
  4. Chronic lymphadenosis

- ADULTS
1. Chronic myelosis
  2. Chronic lymphadenosis
  3. Acute myelosis
  4. Acute lymphadenosis

In children, at least, the relationship of incidence according to sexes, is three males to two females.

In going over the clinical picture one becomes impressed with the fact that by far the most frequent complaint in early cases is "weakness, lassitude, listlessness and pallor." In more advanced cases it is "emaciation, enlarged

Fig. 4.—Authors' case. Drawing from oil immersion study of blood smear. Actual field.

abdomen" and very frequently "inability to lie on the left side." The spleen is always markedly enlarged, while hepatic enlargement varies from "slight" to "very marked."

A very striking feature of the history in a large majority of cases are numerous infections, from which the children had suffered previously, not infrequently with one infection following immediately upon another (see Cases 8 to 23). In fact a history of several infections succeeding each other at short intervals should always call for a thorough blood examination.

Adenopathy is not a frequent or a prominent symptom, and neither is fever.

The blood picture in chronic myelosis has been described innumerable times, and everyone is acquainted with the high leucocytosis, the immature granulocytes (metamyelocytes, myelocytes, promyelocytes and myeloblasts) and the increase in eosinophiles and basophiles (Fig. 4). In children, there is, perhaps, a greater frequency in the appearance of the youngest or myeloblast forms. This is probably to be accounted for by the great irritability of the hemo-

poietic system in children. The aleucemic form of the disease is quite rare. Anemia is always present and, frequently, is quite severe. It appears from the perusal of the literature that many cases reported as chronic myelosis were in reality cases of von Jaksch-Hayem disease.

Prognosis as to life is, of course, hopeless, and as to duration, variable, some cases lasting as long as five and six years, while others, especially those with a subleucemic count, lasted from a few months to two years.

In treatment, benzol, thorium and deep therapy are variable in their effects on different patients, but as a rule, they always react well to the x-ray treatment, the blood picture promptly changing toward the normal for varying periods of time. At times the anemia is so severe as to require several transfusions (authors' case). In connection with the latter it must be pointed out that toward the end of the disease accidents will occur despite the care with which the grouping and compatibility tests are carried out. Undoubtedly, they are due to some reaction on the part of the leucocytes, since according to Doan<sup>7</sup> there is a definite increase in the fragility of these cells in leucemias.

Just prior to death there almost always appear signs of hemorrhagic diathesis.

#### SUMMARY

1. There is presented an additional case of chronic myelosis in a child of nine years who responded to treatment for two years, and then succumbed following his sixth transfusion, due in all probability to the increased fragility of the leucocytes.

2. Thirty other authentic cases of chronic myelosis in children are collected from the literature and presented in Table I.

## STUDIES ON THE QUANTITATIVE ESTIMATION OF BILE PIGMENTS\*

E. A. PETERMAN, M.D., AND THOMAS B. COOLEY, M.D., DETROIT, MICH.

IN 1916, Hooper and Whipple<sup>1</sup> developed a quantitative modification of Salkowski's<sup>2</sup> test for bile pigments whereby bilirubin and biliverdin were estimated together. They diluted specimens of bile with a nitro-hydrochloric acid alcohol mixture† and after about 18 hours estimated colorimetrically the characteristic blue green color that had developed on standing. In 1921, Rous and McMaster<sup>3</sup> introduced an inorganic standard‡ to replace the original artificial color wedge§, and later Sribhishaj, Hawkins, and Whipple<sup>4</sup> adopted the use of a monochromatic light filter in reading the intensity of the color in the solutions. Verifying the observations of Whipple and his associates, Riegel, Johnston, and Ravdin<sup>5</sup> in 1932 found that increasing the temperature hastened the reaction. They also found that the "characteristic blue green" color developed long before the maximum intensity was reached.

Further work in this laboratory on the estimation of bile pigment revealed significant inherent errors in current methods, the results of which emphasize the need for this study of the fundamental principles involved in the colorimetry of bile. For example, the time required to develop the color change with the acid alcohol mixture was far too variable to set any definite time at which to make colorimetric readings. One specimen of the acid alcohol may produce the complete color change in less than an hour while another may require more than a week. The color formed in from eighteen to

\*Received for publication, June 27, 1933.

‡Two c.c. conc. HCl, 0.1 c.c. conc. HNO<sub>3</sub>, and 100 c.c. 95 per cent ethyl alcohol.

§Ten c.c. 10 per cent copper sulphate plus 0.075 c.c. of 1 per cent potassium bichromate.

¶Made with copper sulphate, India ink, and gelatin agar. On cooling the wedge was sealed with vaseline and standardized against pure bilirubin.

twenty-four hours presents such a wide variety of green shades that frequently colorimetric comparisons are impossible without grossly violating the general laws of colorimetry.<sup>6</sup> At times, the color may be yellowish green, deep green, blue green, or blue. The standard of copper sulphate and potassium bichromate is a constant shade of blue green so that the shade of the unknown rarely matches that of the standard unless perchance by accident. There are also many different shades of blue green, and accurate comparisons are difficult, if not impossible, even when that color is produced. The original standard was prepared by Rous and McMaster<sup>3</sup> with 10 per cent copper sulphate to which they added, immediately preceding the quantitative colorimetric readings, more or less potassium bichromate as the occasion required in order to shift the tint of the standard to correspond with that of the individual unknown. It has been found that their procedure of changing the standard to match the shade of the unknown does materially alter the results. Sribhishaj, Hawkins, and Whipple<sup>1</sup> employing the Wratten Monochromatic Light Filter No. 72<sup>4</sup> found that readings could be made without delay, thus obviating the trouble of adjusting the standard to match each individual pigmentary solution. Their results involved the same error as Rous and McMaster's owing to the type of filter applied. The blue rays only are transmitted with Filter No. 72 which absorbs all other light rays, thereby obliterating the shade of color and permitting the observer to compare the blue intensity of any solution with that of a blue or blue green standard. Since the pigmentary value of the yellow intensity is not recorded, when varying quantities of yellow bichromate are added to the blue copper sulphate standard and when a light filter which records the blue intensity only is used, it seems reasonable to assume that the failure to record the yellow color is a source of an appreciable experimental error.

Although bile is potentially a polychromatic fluid, bilirubin is the parent chromogenic substance, and only those colors which are directly concerned with the oxidation reaction of pure bilirubin are considered in this study. When the pure pigment is dissolved in a simple oxidizing solution, the color change progresses from yellow through green and blue to an ultimately colorless solution. Proper classification of these colors is prerequisite to a better understanding of the colorimetric procedure which follows. The present scientific classification of all color is based on the discovery of the solar spectrum<sup>7</sup> in 1666 by Sir Isaac Newton, who found that sunlight was composed of many colors, which could be separated when the sun's rays were allowed to pass through a glass prism. Working with Newton's discovery, Sir David Brewster<sup>8</sup> in 1831 showed that the visible spectrum contained only three primary colors, namely, red, yellow, and blue. By means of light filters, which he had developed in 1822,<sup>9</sup> he demonstrated that the orange, green, and violet colors of the spectrum were secondary, produced by the overlapping of red and yellow, yellow and blue, and blue and red rays, respectively. The fundamental principle that green is a secondary color composed of two primary colors, yellow and blue, was utilized in the present study in the preparation of standards for the colorimetric estimation of all

green shades developed by the oxidation of bilirubin. This principle is applied by the quantitative separation of the yellow and blue intensities from a composite green solution by means of monochromatic light filters.<sup>2</sup>

*Experimental Procedure.*—A series of dichromatic green standards were prepared by combining definite quantities of yellow and blue dye solution.<sup>†</sup> The yellow dye was standardized against a known amount of pure unoxidized bilirubin<sup>‡</sup> and the blue against the maximum blue intensity developed from an equal quantity of oxidized bilirubin. These solutions were then mixed so that each successive standard contained the equivalent of a 10 per cent increase in blue and a compensating 10 per cent decrease in yellow. The resulting ratio of yellow to blue produced therefore a different shade of green in each member of the series. The Wratten Filter No. 76 was used for standardizing and reading the yellow in the solutions and No. 72 was used for the blue.

With these standards, an attempt was first made to ascertain the causes of the difficulties encountered with Hooper and Whipple's acid alcohol mixture, and second to devise an accurate method for determining bile pigment. A quantitative study of the color change in all phases of the reaction was developed along two major lines, namely, the factors which influence the reaction velocity and those which control the variation in shades. With the aid of light filters, experiments on the time required to complete the color changes were made with various oxidizing solutions as well as with different types of nitric acid as the oxidizing agent. Observations were also made upon the effect of temperature and light. The reaction velocity was determined by the amount of blue developed during any given period of time and the end

\*The Wratten Monochromatic Filter No. 72, when placed over the eyepiece of the colorimeter allows the observer to record only the intensity of the blue rays. With the Wratten Monochromatic Filter No. 76, one records only the intensity of the yellow rays.

These filters were obtained from the Eastman Kodak Co., Rochester, N. Y.

†Preparation of Standards.—

I. Stock solutions:

1. Pure bilirubin, 25 mg. in 100 c.c. of chloroform.
2. Dimethylamidoazobenzene, 32 mg. in 100 c.c. ethyl alcohol.
3. Nile blue sulphate, 7.5 mg. in 100 c.c. ethyl alcohol.
4. Nitrohydrochloric acid alcohol<sup>1</sup> made with strictly fresh nitric acid.

II. Standardization of diluted stock solutions:

1. Dilute 20 c.c. of the stock yellow dye to 500 c.c. with alcohol.
2. Dilute 20 c.c. of the stock blue dye to 500 c.c. with alcohol.
3. Expose the nitrohydrochloric acid alcohol solution to ultraviolet light for three minutes at 18 inches from the quartz mercury vapor tube. Stir the solution every fifteen seconds. The depth of the solution not to exceed 5 cm.
4. From a microburet, measure 1 c.c. of the stock bilirubin solution into each of ten 25 c.c. volumetric flasks.
5. Dilute 5 flasks to the mark, with plain ethyl alcohol.
6. Dilute the other 5 flasks to the mark with the treated nitrohydrochloric acid alcohol solution. Allow to stand one hour, at which time they should all be steel blue in color.
7. With the first 5 flasks of unoxidized bilirubin solutions as standards, determine the bilirubin equivalent of the yellow dye. If the average for the series does not closely approximate the known amount of bilirubin, adjust the intensity and restandardize. Use light filter No. 76.
8. With the second 5 flasks of oxidized bilirubin, determine the bilirubin equivalent of the blue dye. Restandardize if necessary. Use light filter No. 72.
9. From a buret measure accurately and mix the yellow and blue dye solutions as follows:

| Standard No. | 0   | 1  | 2  | 3  | 4  | 5  | 6  | 7  | 8  | 9  | 10  |
|--------------|-----|----|----|----|----|----|----|----|----|----|-----|
| C.C. Yellow  | 100 | 90 | 80 | 70 | 60 | 50 | 40 | 30 | 20 | 10 | 0   |
| C.C. Blue    | 0   | 10 | 20 | 30 | 40 | 50 | 60 | 70 | 80 | 90 | 100 |

10. Label each standard according to its value in terms of oxidized and unoxidized bilirubin.  
<sup>†</sup>Obtained from the Eastman Kodak Company, Rochester, N. Y.

of the color change was determined by that point at which the maximum blue intensity was reached. The green color in all phases of the oxidation reaction was recorded in terms of both yellow and blue which permitted a study of the relationship of shade to the ratio existing between the two primary colors. It was then possible to determine the percentage of oxidized bilirubin both by the increase in the blue intensity and by a decrease in the yellow. A few typical experiments are reported.

*Experimental Data.*—The characteristic color change which takes place when pure bilirubin is dissolved in a simple oxidizing solution is due to its combination with oxygen from either the solution or the surrounding atmosphere. The speed with which the reaction takes place depends upon the oxidizing agent and a definite relationship exists between the reaction velocity and the availability of the oxygen. The oxidizing solutions which furnish this element in a readily available form bring about the color change without delay, while the more stable reagents which release the oxygen slowly or with difficulty produce the color transformation at a correspondingly retarded rate.

The observations on nitric acid were especially significant since it has been the reagent of choice in the quantitative estimation of bile pigment. Although it is a powerful oxidizing agent, the oxygen may not always be in a readily available form, a fact which explains the extremely wide variations found in the oxidation reaction time with bilirubin. The amount of oxygen which is free to unite with the pigment depends upon the decomposition of the acid which liberates variable quantities of nascent oxygen and nitrogen dioxide on long-standing, with heat or in sunlight. Consequently, these three factors control the reaction velocity. A specimen of nitric acid which was partially decomposed by standing in the laboratory for about a year, when made up in the usual acid alcohol mixture developed the "characteristic blue green" color in fifteen minutes. This is shown by the first solution in Table I which had actually undergone 95.1 per cent oxidation in that time. In contrast, strictly fresh nitric acid always required more than a week to complete the oxidation reaction as shown by Solutions 3 and 4, which were only 72.4 and 79.5 per cent, respectively, oxidized in seven days. Different specimens of ordinary nitric acid produced various results in the reaction time, depending upon the degree of decomposition of the acid, but always ranging within the extreme limits of fifteen minutes on the one side to a week on the other. Some specimens produced the "characteristic blue green" color in from twelve to eighteen hours as reported by Hooper and Whipple,<sup>1</sup> while others required from eighteen to twenty-four hours as given by Rous and McMaster.<sup>3</sup> Most specimens, however, brought about the color alteration at an entirely different velocity, *characteristic of the particular type of nitric acid.*

By comparing the typical results recorded for Solutions 2 and 3, it may be noted that ordinary daylight in the laboratory had no effect in hastening the color change, whereas heat increased the reaction by facilitating the decomposition of the nitric acid as shown by Solutions 3, 5, and 6. Solutions 5 and 6 incubated at 38° C. were 64.6 and 59.0 per cent, respectively, oxidized in

twenty-four hours, whereas Solution 3, as a control at room temperature, was only 32.9 per cent oxidized in the same length of time. This gives an increase in the reaction velocity of 96 and 79 per cent respectively due to increased temperature. Certain specimens of nitric acid produced the complete oxidation of the bilirubin in four hours at 38° C. as reported by Riegel, Johnston, and Ravdin.<sup>5</sup> At that temperature, however, strictly fresh nitric acid always required more than three days to complete the color change, thus emphasizing that heat is only one of the three determinative factors in bringing about the color transformation by the liberation of oxygen from nitric acid.

Irradiation of the acid alcohol mixture with ultraviolet light produced the same changes in its reaction time with bilirubin as did sunlight, heat, or long-standing. Preliminary observations showed that the nitric acid was the only constituent in the acid alcohol mixture that was influenced by this treatment. Bilirubin, however, was rapidly decolorized by irradiation, making it necessary to observe every precaution in preventing the light rays from coming in contact with the pigment, and therefore treatment of the acid alcohol mixture was carried out in another room. With ultraviolet light, it was possible to regulate at any desired speed the oxidation reaction velocity of fresh nitric acid with bilirubin. Irradiation of the acid alcohol for ten minutes brought about the complete color change in four minutes, but at this velocity a lowering of the maximum blue intensity occurred from loss of pigment by rapid oxidation. The time of exposure was gradually decreased until it was found that treatment of the acid alcohol for three minutes produced the maximum blue intensity in forty-five minutes with no appreciable loss of pigment, while the same solution without irradiation required more than seven days. Light treatment for two minutes developed the complete color change in four hours and for one minute in eighteen hours, showing a direct relationship between the length of time the acid alcohol mixture was exposed to ultraviolet light and the reaction velocity of the oxidation of bilirubin.

Comparison of the curves in Chart 1, which records the development of the blue intensity by the oxidation of bilirubin with nitric acid after one, two, and three-minute exposure of the acid alcohol mixture to ultraviolet light, showed that the contour was essentially the same as curves recording the effects of heat or long-standing on the same solution. The time required to complete the oxidation reaction was the only variation, a fact which is illustrated by superimposing the control curve, plotted in hours instead of minutes, over a curve having a more rapid velocity accelerated by irradiation (Chart 1). In all instances, the oxidation reaction velocity was comparatively rapid early in the process, becoming slower as the supply of available oxygen diminished. Calculations made from the data recorded for Solution 3, Table I, show that the strictly fresh nitric acid used in this solution accomplished 45.5 per cent of the total oxidation during the first twenty-four hours, and 14.4 per cent in the second twenty-four hours with an average of 8 per cent per day for the remainder of the week. When the nitric acid was sufficiently decomposed with ultraviolet light, as shown in Curve 3, Chart 1, the supply

of oxygen set free was sufficient to bring about the complete color change without delay, whereas when the oxygen was released slowly by the more stable specimens of nitric acid, complete oxidation of the bilirubin was greatly prolonged. Insufficient decomposition of the acid by irradiation, formed the blue intensity early with increased speed, carrying the first portion of the curve relatively high, depending upon the amount of liberated oxygen, which as it became exhausted, checked the velocity of the reaction, causing the blue intensity to rise much more slowly later, as shown by Curves 1 and 2. Regardless of the degree of decomposition of the nitric acid, the trend of the curve was always progressively upward until the point of maximum blue intensity was reached.

These observations on the development of the blue intensity are of special interest in relation to the various shades of green formed. For purposes of description one may divide the complete oxidation reaction of bilirubin into four arbitrary phases, based upon the value of the blue in-

Chart 1.—Illustrating in Curves 1, 2 a development of the blue color which have been exposed to ultraviolet light for one, two, and three minutes, respectively. Each curve is divided into different stages: The first stage, which is represented by the heavy solid line, is the yellowish green phase, during which the yellow intensity predominates over the blue; the second stage, which is represented by the heavy broken line, is the blue green phase, during which the blue intensity predominates over the yellow; the third stage is the steel blue, during which the blue color remains at its maximum; the fourth stage, which is represented by the heavy dot and dash line is the phase during which the blue gradually fades out. The light solid line, O, shows the oxidation of bilirubin by the control or untreated acid alcohol mixture; the light dash and circle curve is marked off in hours instead of minutes and represents the slow oxidation of the control solution over a period of six days.

tensity as an index to the extent of the oxidation: the first, comprising all the various shades of yellowish green, begins with the oxidation of the first molecule of bilirubin and ends when 50 per cent of the pigment has been oxidized; the second, consisting of all the various shades of blue green, begins as a continuation of the first stage and ends at the point of maximum blue intensity, indicating complete oxidation of the bilirubin; the third represents that portion of the oxidation reaction during which the blue intensity remains maximum; the fourth, as shown at the end of Curve 3, illustrates the gradual fading out of the blue color (Chart 1). The color change as defined in this paper comprises the first two stages, since the third is constant and the fourth stage is characterized by a fading out of the blue color. The "characteristic

blue green" color described by Hooper and Whipple<sup>1</sup> appears early in the second stage, long before the maximum blue intensity is reached, an observation also made by Riegel, Johnston and Ravdin.<sup>5</sup> Since the former investigators used the intensity of the blue color during this stage as a base for their calculations in the quantitative estimation of bile pigment, one should note that consecutive quantitative estimations are not constant when made upon the blue intensity of the same solution during the blue green stage. This observation is also illustrated by Solution 8, Table I, which grossly was definitely well advanced in the blue green stage long before the initial two-hour reading was made, but showed an increase of 15.8 per cent in the blue intensity during the second two-hour period. From the foregoing observations one may conclude that the blue green color represents a stage of incomplete oxidation of the bilirubin, and quantitative estimations calculated upon the basis of the blue intensity only, do not represent the total pigment content because the unoxidized bilirubin remains unrecorded.

Chart 2.—Illustrating the quantitative relationship between the yellow and blue intensities in the same green solution during the color change produced by the progressive oxidation of pure bilirubin with nitrohydrochloric acid alcohol mixture. The heavy solid line shows the first stage, during which the yellow is greater than the blue and the various shades of yellow green appear. The rapid fall in the yellow was quantitatively compensated for by an equally rapid rise in the blue, so that the two curves met when exactly one-half of the bilirubin was oxidized. The heavy dashed line which represents the second stage in the oxidation of bilirubin begins at the point where the two curves cross or at the point where the blue begins to progressively predominate over the yellow and forms the various shades of blue green.

In order to understand more fully the significance of the various shades of green formed by the oxidative process, studies on the yellow intensity were a necessary counterpart to the studies on the blue. Companion quantitative studies were therefore made of both the yellow and the blue intensities on the same solution, as shown in Chart 2, which illustrates the typical incomplete reaction of nitric acid with bilirubin. The curve representing the quantitative value of the yellow intensity is practically an inverted mirror image of the blue and barring the slight unavoidable experimental errors in quantification could be inverted and superimposed upon the line representing its counterpart. The rapid fall in the yellow intensity was quantitatively compensated for by an equally rapid rise in the blue, so that these two curves crossed when exactly half of the bilirubin had been oxidized, indicating that yellow and blue are the only primary colors involved in the oxidation reaction.

This observation agrees with the statement made earlier in this paper that green is a secondary color composed of two primary colors, yellow and blue. The solution was a perfect deep green color at the point at which the curve for the yellow intensity crossed that of the blue, for at this point the values of the two intensities were colorimetrically equivalent. Up to this point, which marks the end of the first stage, the yellow intensity quantitatively predominated over the blue and the solution developed a variety of yellowish-green shades subject to the extent of the oxidation. Following the point of pigment equilibrium which was marked by the perfect green color, the blue became more and more dominant over the yellow as the oxidation progressed, developing an apparently even greater variety of blue green shades because of the slower reaction velocity during the second stage. Due to rapid oxidation early in the reaction, the first stage lasted only twenty-two minutes, whereas the second occupied several hours, finally reaching the stage of maximum blue intensity when the last traces of yellow had disappeared from the solution.

The relation of the predominant primary color to the recessive one depends upon the extent of the oxidation and control the exact shade of green developed throughout the oxidation reaction of bilirubin. By a study of the data presented in Table II, one finds this relationship to be an inverse ratio, which explains how gentle oxidation through a gradual fall in the yellow intensity and a compensating rise in the blue insidiously changes one shade of green to another. Theoretically, the shade of green is never twice the same during the continuous reaction. One can readily see that unless the reaction velocity of each solution were exactly the same, the shades would be different. This explains the difficulties encountered when matching green bile pigment solutions against one another in the colorimeter. It also explains why a series of green standards with the primary colors mixed in an inverse ratio are essential for accurate colorimetric estimation of all the possible shades of green that may be developed.

By quantitatively estimating the components of the green color separately and combining the results as recorded in Table II, one finds that the estimated value of the yellow intensity plus the blue corresponds closely to the known amount of pigment in the initial solution, a finding of practical importance in the quantitative estimation of bile pigment. With this method, regardless of the shade of color or the extent to which the bilirubin is oxidized, providing it has not yet passed the stage of maximum blue intensity, the pigmentary value of the solution can be accurately estimated at any time during the oxidation reaction. The experimental error, however, was increased slightly at the beginning and at the end of the color change, probably due to the physical difficulty of reading small amounts of yellow in a predominantly blue solution and vice versa, whereas no difficulty was encountered where the yellow to blue ratio was more equalized.

The importance of considering the yellow intensity in the quantitative estimation of bile pigment is reflected in Table I by a comparison of the experimental error recorded after estimating solutions with a known pigment content, both by the older method and by those used in this investigation.

\*Calculated as the average decrease per minute for the preceding five minutes.

For example, when Solution 3 was estimated in twenty-four hours, by the copper sulphate and potassium bichromate standard with Filter No. 72, which records the intensity of the blue color only, the estimated pigmentary value was found to be 0.320 mg. per cent, giving an error of 69.23 per cent. In contrast, when compared in the colorimeter with standard No. 3, the same solution was found to be 32.7 per cent oxidized with a yellow and blue concentration of 0.692 mg. and 0.341 mg. per cent respectively, giving a total pigment content of 1.033 mg. per cent, with an experimental error of 0.67 per cent. This table illustrates that the yellow intensity in the green solutions which corresponds to the unoxidized bilirubin fraction if ignored is recorded as a part of the experimental error.

The observations on the green color formed by the oxidation of bilirubin made during this investigation differ somewhat from the usual impressions given in the textbooks. It is generally implied that biliverdin is the direct oxidation product of bilirubin. These experiments do not entirely contradict this, but tend to explain the manner in which the color of biliverdin is actually formed. The total oxidation of bilirubin completely transformed the yellow solution to a blue color commonly known as bilieyanin, while the partial oxidation formed a great variety of green shades, depending upon the extent of the oxidation. Based upon the present scientific classification of colors, these studies indicate that biliverdin is a mixture of bilirubin and bilieyanin rather than a definite entity. Coordinate quantitative studies on both the yellow and the blue intensities in the same solution illustrate that the oxidation reaction which was characterized by a gradual and progressive shifting in color from yellow through green to blue was accompanied by a quantitative transformation of bilirubin to bilieyanin.

#### SUMMARY

Stimulated by difficulties encountered in the colorimetric methods for the quantitative estimation of bile pigments, a study of the quantitative color change through all phases of the oxidation of bilirubin has been made. The factors influencing the reaction velocity of the oxidation of bilirubin, and the factors controlling variations in the resultant shades of green, yellow green and blue green have been investigated by the preparation and use of a series of suitable standards which are composed of definite mixtures of stable blue and yellow dyes.

It was found that the time required to complete the color change from yellow to deep blue varied with the specimens of nitric acid employed which in turn differed in their supply of free oxygen. External factors such as heat, light, and ultraviolet irradiation influenced the rate of oxidation of bilirubin by virtue of their direct effect upon the liberation of free oxygen from the nitric acid. The blue green color generally employed in colorimetric determinations represents a stage in the incomplete oxidation of bilirubin, and hence determinations based upon this method do not quantitatively represent the amount of bile pigment present in the solution. However, by the quantitative estimation of both the blue and the yellow components, with the aid of light filters and suitable dichromatic standards, the total amount of pigment

in the original solution can be accurately determined at any stage in the oxidation reaction. These experiments indicate that the bile pigment generally designated as biliverdin is a mixture of bilirubin and its oxidation product bilieyanin.

The authors take great pleasure in expressing their sincere appreciation to Icie G. Maey, Ph.D., for her generous aid during the course of this work.

## DEMONSTRATION OF PENETRATION OF AN ANTISEPTIC DYE INTO THE TISSUES OF THE GENITOURINARY TRACT\*

ALFRED GOERNER, M.D., AND FRANK L. HALEY, M.D., BROOKLYN, N. Y.

IN VIEW of the fact that the effective results of a urinary antiseptic may be conditioned not only by concentration in which it is bacteriostatic and bactericidal, but also by the ability of the compound to penetrate into the tissues, it was considered to be of some interest to demonstrate such penetration into the tissues lining the genitourinary tract.

Experiments to show such penetration were carried out as follows: Irrigations of urethra and bladder were made on a series of male rabbits, using a 0.5 per cent solution of the dye. This was supplemented by injections into the pelvis of the kidney via ureter before removal of the entire genitourinary tract. The dye used for these experiments was phenyl-azo-diamino-pyridine hydrochloride (pyridium).

In the preparation of histologic sections, difficulty was encountered in preventing the dye from being leached out of the tissues by the various agents used for fixation, hardening, imbedding, and clearing. After numerous experiments with different procedures, it was found that the most satisfactory method was one in which the tissues were fixed in mercuric chloride solutions

\*From the Department of Biological Chemistry, Long Island College of Medicine.  
Received for publication, May 10, 1933.

and then frozen sections cut, mounted, and immediately photographed. Although other metallic salts also are capable of precipitating the dye, all were found to be more or less unsatisfactory due to the fact that subsequent manipulations of the section leached out the dye from the tissues. Similar objec-

tions were encountered in the case of the alkaloidal reagents, such as picric acid and Lugol's solution, which precipitate the dye, or in the case of alkalis which precipitate the free base.

Mercuric chloride was finally selected since it produced the least soluble, as well as the most highly colored precipitate even in fairly dilute solutions. Before making this selection various other standard fixatives were tried, but

difficulty was always encountered either because the dye was not precipitated or was in fact leached out of the tissues by the fixing solution. Although mercuric chloride was found to be the best precipitant and fixative ordinary imbedding processes involving the use of alcohol and alcohol-ether mixtures for purposes of dehydration were found to bring about solution and diffusion of the mercuric compound of the dye into other nonstained parts of the tissues. The most suitable method for demonstration of the true extent of penetration was found to be as follows: Small portions of excised tissue are placed in bichloride solution for twenty-four hours, frozen sections are then cut, the sections floated in bichloride solution, mounted in glycerin, and photographed.

Fig. 1 is a cross-section of the urethra under low power magnification and shows the mercuric precipitate of the dye. Figs. 2 and 3 are sections of bladder wall under low power magnification showing precipitated dye in the tissues. Fig. 4 is also a cross-section of the bladder wall under high power magnification and may be compared with Fig. 5 which is a similar section of normal bladder wall. Fig. 6 is a cross-section of the ureter showing precipitate of the dye and should be compared with Fig. 7, a section of normal ureter. Fig. 8 is a section of kidney tissue adjacent to the pelvis of this organ and shows dye precipitate, whereas Figs. 9 and 10 are sections of deeper portion of the kidney and show no penetration.

## SOME EXPERIMENTAL STUDIES ON NEMBUTAL (PENTO-BARBITAL-SODIUM)<sup>2</sup>

M. W. HEMINGWAY, M.D., J. VAN DE ERVE, M.D., AND J. D. BOOTH, PH.C.  
CHARLESTON, S. C.

IN TESTING a constant pressure apparatus, with which we wished to be able to inject glucose solutions intravenously at a definite rate over long periods of time, it was found convenient to employ an anesthetic. Nembutal was selected, because of its rapidity of action, and shorter acting time than the other barbiturates. Urine was to be collected and tested for reducing substances. It was observed that very little urine was obtainable during the period of narcosis.

Fee<sup>1</sup> has shown that water diuresis established in decerebrate dogs, by the administration of water through the stomach tube, is checked by the administration of chloroform, ether, chloralose, or morphine in doses commonly employed to produce anesthesia, and the inhibition lasts, roughly, for the same length of time as the narcotic effect.

Frey,<sup>2</sup> in his experiments on rabbits, using urethane, chloral hydrate, and morphine, found that diuresis was decreased whether the water was administered by mouth, by rectum, or through an intestinal fistula.

Ogden<sup>3</sup> demonstrated the inhibition of water diuresis by amytal, and Marx<sup>4</sup> concluded that amytal had a strong antidiuretic effect on dogs, and moreover may cause a retention of substances in the blood ordinarily excreted through the kidneys.

Swanson and Shonle,<sup>5</sup> in their pharmacologic study of nembutal (pento-barbital-sodium), pointed out the fact that nembutal is an isomer of amytal, the difference being in the alkyl side chain, the methyl group in the amytal molecule being attached to the  $\gamma$ -c-atom of the side chain, while in the iso-amytal molecule the methyl group is linked to the  $\alpha$ -c-atom. The position of this methyl group seemingly has a great influence on the physiologic activity.

The disputed question as to the effect of amytal on blood sugar<sup>6, 7, 8, 9, 10</sup> raised the question as to the effect of pento-barbital-sodium on the blood sugar level of a fasting animal.

Hines, et al.,<sup>11</sup> showed that a greater hyperglycemia and a marked increase of glycosuria existed when glucose solution was injected intravenously under amytal anesthesia than in the control experiments on the same animal; whereas Brill<sup>12</sup> concluded that sodium amytal had a marked inhibiting effect on the hyperglycemia produced by morphine.

## EXPERIMENTAL

Five mongrel dogs in normal condition, so far as could be determined by blood and urinary laboratory methods and physical examination, were used.

Each dog received 1 c.c. (1 c.c. = 1 gr.) nembutal (pento-barbital-sodium, Abbott) per 5 pounds body weight. The dogs varied from 14 to 27 pounds in weight. The dogs were fed their usual kennel rations at 2:00 P.M. and received no feeding other than water, which was always accessible. They were accustomed to the laboratory and any excitement was avoided as much as possible.

The next morning, about sixteen or eighteen hours after last food given, they were brought into the laboratory, and 3 c.c. of blood was obtained by venous puncture of the saphenous vein, and oxalated to prevent clotting. Serum was obtained by allowing 2 c.c. of blood to clot.

Water ranging from 200 c.c. to 300 c.c., depending on the size of the animal, was given by stomach tube. The bladder was emptied immediately, and emptied at twenty-minute intervals thereafter, and the amount measured and recorded. Normals for urinary output under water diuresis, blood sugar, urea, nonprotein nitrogen, and total serum protein were obtained for each dog.

The blood samples were secured at approximately hourly intervals, and until such time as the animals indicated that they were reacting well from the anesthesia as manifested by attempts to raise head, stand, etc.

The nembutal was injected intravenously at such a rate that the animals were unconscious at the termination of the injection. During the injection, the respiration always quickened. Injecting too rapidly produced a rapid, jerky respiration. The respiration became slow, full, and deep as soon as the animals were unconscious. There never was any period of excitement, and the same results were always obtained on subsequent injections on the same animal.

On the dosage given, 1 c.c. per 5 pounds (1 c.c. = 1 gr.), a surgical anesthesia was obtained in about five minutes and persisted from forty-five to fifty minutes. The dogs remained asleep a variable length of time, but all were showing definite signs of awakening within three and a half hours and usually were on their feet in four to four and one-half hours with only slight ataxia and incoordination persisting.

The normal urinary output, and the output under nembutal anesthesia, have been charted (Chart 1) for each dog to show the decrease in the urinary output.

Only one record for each dog is shown to avoid confusion on the chart, but several records on each were made, and all responded in a like manner. Increasing the dosage of nembutal, as little as 0.5 c.c. resulted in a greater decrease in the urinary output. In Dog 17, increasing the dosage from 3 c.c. to 3.5 c.c. resulted in anuria during the period of narcosis.

With an increase in the total dosage of nembutal a longer period of anesthesia resulted, both in the period of surgical anesthesia and in the time in which reaction was first noted.

In only one instance (Dog 10) did an active diuresis seem to begin after the animal began to react. It is possible that during the longer time in which

narcosis is present sufficient water is lost by other routes, other than through the kidney, so that there is not sufficient excess water present to produce an active diuresis.

Marx, II.<sup>13</sup> states that amytal has an influence on the cerebral centers, regulating metabolism of water, and that it also influences the endothelium of the capillaries, changing the permeability; from which he concluded that the hypnotic directs the water to the tissues of the body in general, instead of

Chart 1

to the kidneys. We are inclined to believe that nembutal has a similar action. This action is not peculiar to the barbiturates alone, as it is possible to produce edema by injecting sodium chloride infusions quite readily, if chloroform, ether, or chloral hydrate has been used to anesthetize the animal.

From Pratt's<sup>14</sup> work, one can infer that the liver breaks down and detoxifies pento-barbital, because in experimental lesions of the liver, produced by chloroform, nembutal in the usual dosage produces prolonged narcosis.

We thought it might be interesting to note the blood chemistry changes, if any, during the period of narcosis, and if repeated injections would result in damage to the liver and kidneys.

Since the blood chemistry studies were in agreement with each dog tested, the results of the study of one dog only are tabulated (Table I).

TABLE I

| TIME       | DOG 10<br>BLOOD SAMPLES | SUGAR—NORMAL | SUGAR DURING<br>NEMBUTAL AN-<br>ESTHESIA | UREA—NORMAL | UREA DURING<br>NEMBUTAL AN-<br>ESTHESIA | T.S.P.—NORMAL | T.S.P. DURING<br>NEMBUTAL<br>ANESTHESIA | N.P.N.—NORMAL | N.P.N. DURING<br>NEMBUTAL<br>ANESTHESIA |

| 12:20 P.M. | Fourth sample           | 74.3         | 88.5                                     | 20.3        | 21.4                                    | 5.9           | 4.41                                    | 26.4          | 23.2                                    |
| 1:20       | Fifth sample            | 76.2         | 90.5                                     | 20.3        | 21.8                                    | 5.7           | 4.71                                    | 26.1          | 24.2                                    |

There was in each instance a slight rise in the blood sugar levels, though not sufficient in our opinion to warrant the conclusion that nembutal raises the blood sugar level. The rises noted might be accounted for by the metabolic changes occurring during that length of time.

Because of the interest and controversy in regard to the effect of amytal on the blood sugar level, the results of the five dogs studied will be tabulated below (Table II).

The blood samples were obtained as follows:

- Sample 1, before giving water
- Sample 2, 20 minutes after giving nembutal
- Sample 3, 1 hour after second sample
- Sample 4, 1 hour after third sample
- Sample 5, 1 hour after fourth sample

TABLE II

## BLOOD SUGAR DURING NEMBUTAL ANESTHESIA

|               | DOG 16 | DOG 10 | DOG 20 | DOG 19 | DOG 17 |
|---------------|--------|--------|--------|--------|--------|
| First sample  | 55.5   | 78.7   | 57.8   | 85.1   | 58.3   |
| Second sample | 58.2   | 103.2  | 66.2   | 93.4   | 68.9   |
| Third sample  | 71.8   | 76.2   | 83.4   | 94.3   | 64.7   |
| Fourth sample | 74.1   | 88.5   | 83.5   | 71.2   | 64.1   |
| Fifth sample  | 66.2   | 90.5   | 75.6   | 71.5   | 63.5   |

In one of our experiments, in which we were injecting a glucose solution, 6 per cent, intravenously, we found the blood sugar level to rise to 256 mg. per 100 c.c., without producing any diuresis. While further experimentation on this point is necessary, it indicates that the inhibition of water diuresis, produced by nembutal, cannot be broken by infusions of glucose at such a rate that the renal threshold is exceeded.

Three of our dogs have received repeated injections (1 c.c. per 5 pounds [1 c.c. = 1 gr.]) at intervals of six days. Dog 16 has had 8 injections and dogs 10 and 19 ten such injections. The animals did not lose weight and their blood chemistries and urinalyses were within normal limits one week after the last injection.

## TO SUMMARIZE

1. Nembutal seems to be an efficient and rapidly producing anesthetic, with no initial period of excitement, with a shorter period of narcosis, and a relatively shorter reacting time than the other barbiturates.

2. Water diuresis in dogs is inhibited by doses of nembutal (pento-barbital-sodium, Abbott), sufficient to produce anesthesia. (Dose: 1 gr. per 5 pounds body weight.) In one of our dogs, increasing the dosage, a complete suppression of urine followed, during the period of narcosis.

3. There is a slight change in the blood sugar during the period of narcosis.

4. Blood chemistry studies, including urea, nonprotein nitrogen, and total serum protein, were not appreciably affected during the period of narcosis.

5. Three dogs, receiving as many as 8 to 10 injections at intervals of six days, showed no changes in hepatic or renal functions that could be detected by the usual blood and urine laboratory examinations.

# THE USE OF HYDROGEN PEROXIDE IN THE QUANTITATIVE ESTIMATION OF BILIRUBIN IN BILE\*

E. A. PETERMAN, M.D., AND THOMAS B. COOLEY, M.D., DETROIT, MICH.

IN A CRITICAL study of the quantitative estimation of bile pigment,<sup>1</sup> it was shown that there are errors in the current colorimetric method<sup>2-5</sup> which are due to the inefficient and variable oxidizing agent employed and the failure to consider the unoxidized pigment fraction which forms a part of the blue green color used in making the colorimetric readings. It was demonstrated that the amount of free oxygen which controls the color change depends upon the degree of decomposition of the different specimens of nitric acid used in making up the oxidizing solution and this in turn produced extremely wide variations in its oxidation reaction time with bilirubin. Consequently, the various degrees of spontaneous decomposition existing in the nitric acid standing in the different laboratories, presents an inconstant variable which renders the results on the quantitative estimation of bilirubin incomparable. Furthermore, it was shown that the changes in the color of the pigment solution were produced by a gradual and progressive oxidation of the bilirubin to bilicyanin and that the green solution commonly known as biliverdin should be considered colorimetrically as a mixture of the two pigments, bilirubin and its oxidation product, bilicyanin, each of which must be estimated separately in order to ascertain the pigmentary value of the green solutions produced in the oxidation reaction.

In the present report an attempt has been made to eliminate the errors due to the variability of the nitric acid by replacing it with hydrogen peroxide which gives a more constant and rapidly available source of free oxygen. The difficulties as well as the errors involved in estimating the pigmentary value of the blue green color are eliminated when the readings are made later in the oxidation reaction, namely, during the stage of maximum blue intensity. The final colorimetric readings with hydrogen peroxide as the source of available oxygen in the oxidizing solution can be made within thirty minutes instead of the former from eighteen to twenty-four hours, thus giving a simplified, rapid and accurate method for the quantitative estimation of the bilirubin in bile.

## PREPARATION OF SOLUTIONS

*Stock Bilirubin Solution.*—Transfer 25 mg. of pure bilirubin† to a clean dry 100 c.c. volumetric flask and make up to volume with chloroform.

*Nile Blue Sulphate Solution.*—Transfer 15 mg. of Nile blue sulphate‡ to a 100 c.c. volumetric flask and make up to volume with 95 per cent ethyl alcohol.

\*Received for publication, June 27, 1923.

†This study was made possible by a grant and the facilities of the Research Laboratory of the Children's Fund of Michigan and the Children's Hospital of Michigan, Detroit.

‡The bilirubin was obtained from the Eastman Kodak Company, Rochester, New York.

§Nile blue sulphate (diethylaminonaphthophenoxazine) ( $C_{20}H_{22}N_2O$ ):  $SO_4$  made by The Coleman and Bell Company, Norwood, Ohio, was used.

**Oxidizing Reagent.**—A solution of 2 c.c. of concentrated hydrochloric acid and 0.4 c.c. of 30 per cent hydrogen peroxide\* is made up to 100 c.c. with 95 per cent ethyl alcohol.

#### STANDARDIZATION OF THE DYE SOLUTION

Transfer 1 c.c. of the stock bilirubin solution into each of five 25 c.c. volumetric flasks and dilute to volume with the oxidizing reagent. After thoroughly shaking allow the solution to stand for thirty minutes at room temperature until the blue color develops. Dilute 10 c.c. of the Nile blue sulphate solution to 500 c.c. with 95 per cent ethyl alcohol. Using the 1 mg. per cent solutions of oxidized bilirubin as standards determine the bilirubin equivalent of the diluted blue dye solution. The average of the five determinations should be taken as the final result. Place the Wratten Monochromatic Light Filter No. 72† over the eyepiece of the colorimeter when making the readings. Calculate the values for the dye solution by the formula as follows:

$$\frac{\text{Reading of standard} \times \text{Concentration of standard in mg. per 100 c.c.}}{\text{Reading of unknown}} = \text{Bilirubin equivalent of the blue dye in mg. per 100 c.c.}$$

**Method for the Determination of Bilirubin in Bile ‡**—Transfer 1 c.c. of the bile to be analyzed to a clean dry 50 c.c. volumetric flask and make up to volume with the oxidizing reagent. After thoroughly shaking allow the solution to stand for thirty minutes at room temperature until the blue color develops. Clear the solution of precipitated mucus in the centrifuge or by filtering and compare intensity of the cleared solution in the colorimeter with that of the stable blue standard. Place the Wratten Monochromatic Light Filter No. 72 over the eyepiece of the colorimeter before making the readings. The calculations are made as follows:

$$\frac{\text{Reading of standard} \times \text{Concentration of standard in mg. per 100 c.c.} \times \text{dilution}}{\text{Reading of unknown}} = \text{Mg. of bilirubin per 100 c.c.}$$

The experimental error of the method with known solutions of pure bilirubin is less than 2 per cent. The variation in results with bile itself, however, is increased at times to nearly 5 per cent due to the inability to deliver aliquot specimens of mucus laden fluid from the ordinary pipette. For this reason triplicate determinations should be averaged in order to reduce the experimental error to a minimum and every precaution should be exercised in uniformly draining the pipette.

\*Merck's hydrogen peroxide, 30 per cent (Superoxol).

†Wratten Monochromatic Light Filter No. 72 was obtained from the Eastman Kodak Company, Rochester, New York. The shade of the final blue color developed from fresh bile for the readings is sufficiently constant to eliminate the use of this filter but frequently the final tint is changed by the presence of other pigments in the gallbladder and this filter eliminates such interferences. Filter No. 72 permits the intensity of the blue rays only.

‡Experiments show that the principles of this method may be applied to the quantitative estimation of bilirubin in serum and urine. Further work is in progress on the details of the technic.

## DISCUSSION

Although bilirubin is the parent chromogenic substance in bile, there may be other pigmentary substances formed on standing through its oxidation, reduction, hydrolysis, or conjugation with other bile constituents. Due to the fact that bilirubin is an unstable pigment, quantitative estimations should be made upon strictly fresh bile before any spontaneous chemical changes occur to cause the loss of pigment. Because of the natural affinity of bilirubin for oxygen, which it quickly absorbs from the solution or the surrounding atmosphere, spontaneous oxidation is frequently the earliest change that occurs in fresh bile and may even take place within the gallbladder, while it invariably occurs subsequent to removal from the body and exposure to the air. Colorimetric studies indicate that bilicyanin, which is the direct oxidation product of bilirubin, is present in greater or lesser amounts in the specimens of bile which have already turned green from spontaneous oxidation. Although both

Chart 1.—Illustrating the four stages in the progressive oxidation reaction of a 1.024 mg. per cent solution of pure bilirubin with the hydrogen peroxide-hydrochloric acid-alcohol oxidizing reagent and the relationship of the two primary colors which form the green solution. The first stage is yellowish green color due to the predominance of the unoxidized bilirubin over its oxidation product, bilicyanin; the second stage is blue green color due to the bilicyanin predominating over the bilirubin; the third stage represents the maximum blue intensity developed from the bilirubin by oxidation and illustrates the most reliable position in the oxidation reaction for quantitatively estimating the total pigment content by means of a single monochromatic blue standard; during the fourth stage the blue intensity gradually fades out.

spontaneous and induced oxidation transform the bilirubin to bilicyanin, it so happens that the oxidizing reacts with both pigments so that the bilicyanin previously formed by spontaneous oxidation may be further oxidized to colorless end-products by the time the remainder of the bilirubin is oxidized to bilicyanin. Experience shows that 2 or 3 per cent of bilicyanin mixed with the bilirubin gives the solution a definite greenish tint, and yet, this amount is within the limits of the experimental error, so that even though the bile specimen is slightly greenish the simple method described above is sufficiently accurate for practical purposes. In specimens which have undergone greater spontaneous oxidation, however, it becomes necessary to make separate colorimetric estimations of the two constituent pigments, bilirubin and bilicyanin, as described in a previous publication<sup>1</sup> and illustrated in Table I.

\*Calculated as the average decrease per minute for the preceding five minutes.

There are four stages in the complete oxidation of pure bilirubin as shown in Chart 1 and Table I. During the first stage, the yellow unoxidized bilirubin predominates over its blue oxidation product, bilieyanin, while during the second stage their ratio is reversed and forms the blue green color generally used in colorimetric comparisons. It has been demonstrated that the blue green color represents a stage of incomplete oxidation of bilirubin, and quantitative estimations made during this stage not only require the determination of the oxidized bilirubin but also the pigment fraction that remains unoxidized.<sup>1</sup>

For such a determination it is necessary to employ the more complicated series of dichromatic green standards which contain the primary colors mixed in an inverse ratio.<sup>1</sup> In contrast, the present accurate yet simplified method for determining bilirubin utilizes the maximum blue intensity of the third stage of oxidation for the colorimetric readings and requires but a single monochromatic blue standard. As the oxidation progresses from the second into the third stage the color changes from the blue green to blue, and the curve for the blue intensity ceases to rise, remaining at the maximum level for considerable time, due to the fact that at this time the available oxygen is nearly depleted and the oxidation velocity is comparatively slow. Since the time limits of the third stage are sufficiently long to permit readings of a series of solutions without undue haste and the blue color remains constant during this stage, it offers, therefore, the most reliable period during the oxidation reaction of bilirubin in which to quantitatively estimate the total pigment content by monochromatic methods.

Through the introduction of hydrogen peroxide to replace the nitric acid in the oxidizing solution, the practicability of using the third stage for the final readings is made possible. Because of its labile oxygen, hydrogen peroxide has the ability to complete the oxidation of bilirubin to bilieyanin within thirty minutes instead of the former eighteen to twenty-four hours. The maximum blue intensity developed with hydrogen peroxide from a known amount of pure bilirubin is remarkably constant, varying only with the amount of pigment in the initial solution. Slight alterations in the amount of hydrogen peroxide do not alter the height of the maximum blue intensity but only serve to increase or decrease the length of time the blue intensity remains at its maximum. The same is true for variations in the hydrochloric acid in the oxidizing solution. In order to make accurate readings on both the yellow and blue colors in the same solution as shown in Chart 1, the reaction time of bilirubin with hydrogen peroxide was prolonged from twenty minutes to fifty-five minutes by reducing the amount of hydrochloric acid in the oxidizing solution from the usual 2 per cent to 1 per cent. With the use of a single monochromatic standard, however, the maximum blue color only is considered, and therefore, the more rapid reaction obtained with higher acid content is the more desirable.

Pure bilirubin may be used as a standard by treating the stock bilirubin solution in the same way as the unknown, but when it is used the solution in the colorimeter cup must be changed with each unknown, as the prolonged catalytic effect of the strong colorimeter light upon the oxidation of the standard

is sufficient to alter the results. Because of this difficulty the procedure is greatly facilitated by using a stable blue dye standard which is not affected by the light. Although the artificial standard is photostabile the oxidation of the pigment in the bile solution is hastened by the influence of strong light, and for this reason the reading of the unknown should be made promptly, once the solution is placed in the colorimeter. A standard composed of an alcoholic solution of an organic blue dye, nile blue sulphate, was found to be preferable to an aqueous solution of the inorganic salt, copper sulphate, which was previously used for this purpose.

#### SUMMARY

A simplified, rapid, and accurate method for the quantitative estimation of bilirubin in bile is presented in which hydrogen peroxide with its more constant and available source of free oxygen has been substituted for the nitric acid in the oxidizing reagent, thus eliminating errors due to the variability of the different specimens of nitric acid. The final colorimetric readings can be made within thirty minutes instead of the usual eighteen to twenty-four hours and at the maximum blue intensity instead of during the variable blue green color stage, making it possible to use a stable monochromatic organic dye, nile blue, as a standard for quantitatively estimating bile pigment.

The authors take great pleasure in expressing their sincere appreciation to Icie G. Macy, Ph.D., for her generous aid during the course of this work.

## A METASTATIC TUMOR OF THE TRICUSPID VALVE ARISING IN A CASE OF MALIGNANT TERATOMA OF THE TESTIS\*

J. R. E. MORGAN, TORONTO, CANADA

THIS report deals with a case of teratoma of the testis in which an unusual tumor growth of the tricuspid valve of the heart was found at autopsy. The mass had produced no symptoms during life, and its presence was not suspected.

The history was briefly as follows: Seventeen months before death, the patient first noticed a swelling in the left side of the scrotum. This tumor grew rapidly, and on removal four months later was the size of an orange. The pathologic report on the specimen was teratomatous tumor of the testis.

Three months later he was readmitted to the hospital with a large mass in the left side of his abdomen. A laparotomy was performed and a large inoperable tumor the size of a grapefruit was found. Sections taken for biopsy were diagnosed secondary teratoma of the abdominal lymph glands. Microscopic sections showed the tumor to consist of a hemorrhagic and necrotic fibrous stroma containing early cartilage cells, cysts, and glands. The lining of the glands was of a low columnar epithelium, while some cysts were lined by a low cuboidal epithelium and others by stratified squamous epithelium.

Following discharge from the hospital, the patient's condition became rapidly worse, and on his last admission three months later, he complained of shortness of breath, pain in the right chest, weakness, and loss of weight. Physical examination revealed almost complete loss of resonance over the right chest, tracheal displacement to the left, clubbing of fingers and toes, and a large abdominal tumor.

At autopsy large tumor masses were found in the abdominal and pleural cavities. These tissues were irregular, soft, and hemorrhagic with many cystic areas scattered throughout the fibrous stroma. The microscopic picture was as above described.

Attached to the tricuspid valve were a number of curious, irregular masses made up of about 20 cystic structures (see Fig. 1). This tumor growth was 6 cm. in length and was firmly attached to the valve cusps, and with each of its cystic structures pedunculated and waving in the blood stream. Most of the tumor consisted of small yellowish white, firm, thick-walled cysts about the size of a match head joined together by fibrous connective tissue. There were also two large thin-walled cysts situated at either end of the mass. These cysts were soft, fluctuant, filled with a clear yellowish, watery fluid and measured 1.3 cm. in diameter.

\*From the Department of Pathology, University of Toronto and Toronto General Hospital.  
Received for publication, June 27, 1933.

The principal tissue of the tumor was composed of a pale staining dense fibrous connective tissue. In some areas it was very compact and acellular, while in others, the wavy fibers were rich in deep staining nuclei, tending to be fusiform in shape.

The tumor masses were covered by a single layer of endothelial cells similar in appearance to those of the normal endocardium. Small thrombus masses

Fig. 1.—Gross appearance of cystic tumor of tricuspid valve.

Fig. 2.—Microscopic section of epithelial lined cyst from tricuspid valve.

were found attached to the surface of the tumor. These consisted chiefly of a loose fibrin meshwork, containing many platelets and leucocytes. In a few areas the endothelial covering of the tumor was broken, and the thrombus was adherent to the fibrous tissue. The tissues were quite vascular.

The sections of an individual mass revealed several small cystic spaces. The lining of these cysts was variable in nature. One was lined in part by a

single layer of low cuboidal epithelial cells and partially by what appeared to be squamous epithelium. The cavity was filled by a small mass of desquamated epithelium. The fibrous connective tissue about the cyst was more dense and cellular than in other areas. One cystic cavity was completely lined by stratified squamous cells. This lining varied in thickness from five to fifteen cells, the upper layers being only slightly flattened. The basement membrane of the epithelium was very poorly defined. Occasionally the epithelium was of columnar character. There were also a few small clumps of cells scattered throughout the sections which presented the picture of early mesenchymal cells, showing a tendency to differentiate into cartilage.

#### SUMMARY

A tumor metastasis upon tricuspid valve is reported, the primary tumor being a malignant teratoma of the testis. The sections examined presented (1) a somewhat acellular fibrous connective tissue stroma, containing large areas of mucoid degeneration covered by a single layer of endothelium upon which were many thrombi; (2) the tissue contained cysts lined by both cuboidal and stratified types of epithelial cells; (3) there were present small capillary spaces filled by red blood cells; (4) small areas of mesenchymal cells suggestive of early cartilage formation were also present.

### THE CAUSATIVE ORGANISMS OF PNEUMONIA IN CHILDREN IN EGYPT\*

---

M. A. GOHAR, M.R.C.P., D.P.H., D.T.M., AND H., DIP. BAC., LONDON, ENG., AND  
M. A. ABBOD, M.B., B.CH., CAIRO, EGYPT

---

THIS work has been undertaken to find out the common causative organisms of pneumonia in children in Egypt for which purpose specimens taken directly by lung puncture at that part which clinically showed most physical signs were sent to the laboratory. The investigation was carried out during the three months from October to December, when pneumonias are most common in Egypt, particularly in the middle part of that period.

Fifty-two cases were available. Thirty-seven were out-patients (25 males and 12 females) and fifteen in-patients (10 males and 5 females). The ages varied from four months to five years.

Thirty-five patients exhibited lobular distribution (8 right, 11 left, and 16 bilateral). Ten were of the lobar type and 6 probably so (10 right and 6 left); one case was of the pseudolobar type (right). Of the former, one was associated with an empyema (syn-pneumonic), two with slight pleural effusion, and one with meningitis probably secondary to the lung condition. Of the lobar cases 3 were complicated with a syn-pneumonic empyema. The disease was primary in 31 cases, definitely secondary to whooping cough in 2, and prob-

---

\*From the Bacteriology and Pediatric Departments, Faculty of Medicine, Cairo.  
Received for publication, January 17, 1932.

ably so in more, and secondary to infections of the upper respiratory tract in 14. In one patient the disease was of a tuberculous origin as verified by postmortem examination, although during life no evidence of tuberculosis was present.

The majority of out-patient cases could not be traced satisfactorily; two of the patients are known to have been cured. Of the in-patients 12 were cured, one improved, and 3 (one of them tuberculous) died.

#### EXPERIMENTAL

The specimens obtained by lung puncture and sent to the laboratory in sterile test tubes were plated out without delay on plates of blood agar and Fildes' peptic blood digest medium, incubated at 37° C. and examined after twenty-four hours and thereafter. To the remaining fluid in the test tubes broth was added, taking the necessary precautions to prevent contamination, and the tubes were likewise incubated at 37° C., so that in case the plated specimens proved sterile, there would still be hope of finding organisms by resorting to the broth cultures. These broth cultures, however, were only resorted to in very few instances, as it was possible in the great majority to obtain growth by primary cultivation. The colonies on these plates were examined, and pure cultures were made. Whenever necessary, biochemical and serologic reactions and pathogenicity tests were performed in order to determine the exact nature of the organism. With such organisms as frankly hemolytic streptococci and staphylococci, obviously such procedure was unnecessary, the appearance of the colonies and the films being quite sufficient. For the differentiation between Pfeiffer's bacillus and Bordet-Gengou's bacillus, the culture characteristics were largely depended upon, the better growth of the former on Fildes' medium and of the latter on Bordet's medium, etc. Sera were not available. Without producing all the protocols, it will be enough to mention that out of the 52 specimens sent for bacteriologic examination, 31 specimens were found to contain one kind of organism, 17 more than one, and 4 were sterile. The results are shown in Tables I and II.

TABLE I

CASES SHOWING THE PRESENCE OF ONE KIND OF ORGANISM. 31 SPECIMENS IN ALL

| NO. OF SPECIMENS | NATURE OF ORGANISM       | PER CENT |
|------------------|--------------------------|----------|
| 8                | Pneumococcus             | 16       |
| 5                | Hemolytic streptococcus  | 10       |
| 7                | Nonhemolytic             | 14       |
| 2                | Staphylococcus           | 4        |
| 5                | Pfeiffer's bacillus      | 10       |
| 4                | Bordet-Gengou's bacillus | 8        |

It will be seen that out of 52 cases, pneumococci were present in 13, hemolytic streptococci in 9, and nonhemolytic streptococci in 11 cases, either alone or in association with other organisms, and that these are evidently responsible for the great majority of cases.

As typing of pneumococci from cases of pneumonias was to our knowledge not done in Egypt, owing to the relative infrequency of pneumonias in adults and the difficulty of obtaining a reasonable number of strains to work with, it

|                              | Nonhemolytic streptococcus and staphylococcus                  | 2            |
|                              | Staphylococcus                                                 | 2            |
|                              | Staphylococcus and <i>Hemophilus influenzae</i>                | 1            |
|                              | <i>H. influenzae</i>                                           | 1            |
|                              | Nonhemolytic streptococcus and <i>H. influenzae</i>            | 2            |
|                              | Hemolytic streptococcus and staphylococcus                     | 1            |
|                              | Staphylococcus and Bordet-Gengou's bacillus                    | 1            |
|                              | Staphylococcus and <i>B. Friedlander</i>                       | 1            |

was thought advisable to do typing on the few available strains of pneumococci isolated from our cases. For typing, sera sent us by courtesy of the Rockefeller Institute were used and for the preparation of emulsions pure cultures on serum agar were employed. The serial method of dilution of serum was adopted, and the mixtures incubated in a water-bath at 50° C. for four hours. The result is shown in Table IV.

TABLE IV

| TYPES OF PNEUMOCOCCUS | NO. OF SPECIMENS | PER CENT |
|-----------------------|------------------|----------|
| Type I                | 2 cases          | 15       |
| Type II               | 3 cases          | 24       |
| Type III              | 2 cases          | 15       |
| Group IV              | 6 cases          | 46       |

It must be admitted that the number of strains is hardly sufficient to come to any conclusion as to the distribution of types of pneumococci isolated from cases of pneumonia in Egypt. It is our intention to proceed with the collection of more strains in order to be able to give more reliable results, but the figures as they are will give an approximate idea about the distribution of the various types.

#### SUMMARY AND CONCLUSIONS

1. Fifty-two cases of pneumonias occurring in infancy and childhood in Egypt were examined, 35 being of the lobular and 17 of the lobar type.

2. The disease was primary as far as the history and examination showed in 3 cases and secondary in the remainder, being secondary apparently to whooping cough in 6, and to infections of the upper respiratory tract in 14.

3. In 31 instances a single kind of organism was found by lung puncture (59.6 per cent); more than one kind of organism were found in 17 cases (32.7 per cent), and the puncture was sterile (7.5 per cent) in 4 instances.

4. Altogether pneumococci were present in 13 cases (25 per cent) and streptococci in 20 cases (38.5 per cent) (hemolytic in 9 and nonhemolytic in 11), either alone or in association with other organisms. These organisms seem to be responsible for most of the cases examined.

5. Of the cases showing one kind of organism, pneumococci were found in 8, streptococci in 12 (hemolytic in 5, nonhemolytic in 7), staphylococci in 2, Pfeiffer's bacillus in 5, and Bordet-Gengou's bacillus in 4 cases.

6. Typing of the pneumococci met with showed 15 per cent of Type I, 24 per cent of Type II, 15 per cent of Type III, and 46 per cent of Group IV, but the limited number of cases prevents us from considering these percentages as final.

We wish to express our gratitude to Dr. I. Shawky and Dr. A. Khalil of the Pediatric Department, Faculty of Medicine, Cairo, for their valuable suggestions.

# LABORATORY METHODS

## A NEW MICROSCOPE ADAPTER FOR THE HAND SPECTROSCOPE\*

AUBREY V. GREAVES, M.B. (TOR.), D.T.M. (LIVER.), HONG KONG, CHINA

IN A recent communication I† described a method for the routine examination of blood stains in medicolegal cases. The method requires spectroscopic examination of suitably treated material on a microscopic slide, and this involves the insertion of the body of a hand spectroscope into the tube of the microscope.

I found that it was not easy to hold the spectroscope steady and at the same time make an exact reading of the wave length scale. I discussed the difficulty with the representative of Messrs. Zeiss & Co. and described to him more or less what was wanted, and the attachment presently described is the result of

\*From the Bacteriological Institute, Medical Department.

†Greaves, A. V.: The Use of Takeyama's Solution in the Identification of Blood Stains, Brit. M. J. 2: 932, 1932.

the leaven of my suggestion working on the dough of their ingenuity. Reference to the figure will show that the body of the spectroscope is grasped by a circular band tightened by a screw with a milled head. This is connected with a heavily built standard, which in turn, is connected by a similar band attachment to the draw tube of the microscope. The spectroscope is thus held rigidly in perfect alignment with the optical system of the microscope. The standard is broken in the middle by a hinge by means of which the spectroscope may be swung away from the observer and thus free use of the ocular permitted. In the illustration may also be seen an attachment with reflecting mirror for use with a comparison prism if the spectroscope is so equipped. This may be removed if desired. The smaller tube containing the wave length scale is also equipped with a small reflecting mirror by means of which a beam of light may be passed up the tube to illuminate the scale. In the photograph the microscopic ocular is shown in place; I have found that it is much better to remove it before observing the spectrum. The method suggested for use of the appliance is as follows: The attachment (which may conveniently be left permanently applied to the spectroscope) is slipped over the tube of the microscope (after removal of the ocular) and the screw on the band tightened, so that the end of the spectroscope tube is just clear of the tube of the microscope. The hinge of the holder is adjusted so as to be on the side of the tube away from the observer. The microscope is now placed accurately in relation to the lighting system and the small mirror at the end of the tube bearing the wave length scale is adjusted so as to illuminate the scale. When these preliminary preparations have been made, the spectroscope may be swung away from the observer and the ocular replaced in the tube and the microscope is then ready for use as soon as the slide preparation is made. When the color change indicative of the presence of blood is observed on the slide (after treatment with Takayama's solution), the ocular is withdrawn, the spectroscope is swung into place and the spectrum observed and the bands located in relation to the scale. The appliance is heavily built, and there appears to be nothing about it which can get out of order or become worn.

## A CENTRIFUGE METHOD FOR THE DETERMINATION OF THE VOLUME OF CELLS IN BLOOD\*

GEORGE M. GUEST, M.D., AND VINTON E. SILER, A.B., CINCINNATI, OHIO

IN RECENT years increasing attention has been paid to the fact that significant changes of the volume of cells in the blood may be observed in a wide variety of pathologic conditions, and that in certain diseases the determination of these changes may afford valuable diagnostic aid. Knowledge of the relative volume of cells, of the red cell count and of the concentration of hemoglobin in a sample of whole blood permits the calculation of two values which are increasingly used in the classification of different types of anemia; namely, the average size of the erythrocytes in cubic microns and the concentration of hemoglobin per unit of volume in the red cells. Reviews of most of the reported studies of this subject may be found in articles by Haden (1931, 1932), Osgood, Haskins, and Trotman (1932), and Wintrobe (1932). The determination of the relative volume of cells in blood also permits the indirect estimation of various chemical constituents of the cells by calculation from determinations made on whole blood and plasma in circumstances where direct chemical study of the cells is less satisfactory.

Numerous methods have been offered for the determination of blood cell volume, but most of them have certain features which present more or less serious obstacles to their general application. Ponder and Saslow (1930) have reviewed many of the methods and discussed the faults inherent in each type of procedure. These authors claimed that their modification of the Stewart (1899) colorimetric method was the most accurate means of determining cell volume, but this method is extremely tedious and the amount of blood required is prohibitive if the bloods of infants or small laboratory animals are to be studied. Although the centrifuge method in its many modifications has been criticized by Ponder and Saslow as well as by others who have studied the problem, this procedure is, nevertheless, generally considered to be the most practical for clinical use. Aside from other advantages, the hematocrit tube has one distinctive point of superiority over other devices, in that it offers the only practical means of measuring separately the total cell volume and the red cell volume. This is important if the cell volume value is used to calculate the size of the erythrocytes or the hemoglobin content of the red cells, since the failure to exclude the large white cells may often introduce into these calculations an easily perceptible error.

Judging by the published reports of cell volume studies, the Van Allen (1925) method appears to be one of the most popular of the several procedures in current clinical use. The Van Allen tube is convenient and is economical of

\*From the Children's Hospital Research Foundation and the Department of Pediatrics, College of Medicine, University of Cincinnati.  
Received for publication, May 24, 1933.

blood, but it has one potential source of error in common with all types of hematocrit tubes with which rubber sealing devices are used; such sealing devices occasionally allow slight leakage which may pass unnoticed, and this danger is increased the higher the centrifuge speed to which the tubes are subjected. Another objection to this method is that the diluting fluid (1.3 per cent sodium oxalate solution) while perhaps isotonic for normal blood, may not necessarily be isotonic for pathologic blood samples in which osmotic changes have occurred. This criticism is applicable to all those methods employing anticoagulant salts which may cause changes of cell volume. Whether a supposedly isotonic oxalate solution is used as in the Van Allen (1925) and Haden (1923, 1925) methods, or whether dry oxalate is used and correction made for shrinkage of the cells, as in the Osgood (1926) and Wintrobe (1929) methods; in either case the constants determined for normal bloods have not been proved dependable for bloods in which osmotic changes have occurred under different pathologic conditions.

Economy of blood is nearly always an important consideration and at times is essential in these studies. Haden (1930) maintained that 10 c.c. of blood—the amount used in his method—was not an excessive amount to take from a patient. This is perhaps true of adults, but it is usually impractical to remove such an amount from infants, especially when more blood is to be drawn for other chemical studies. In discussing various methods Haden also claimed that a macromethod was necessary for accuracy, but in our own experience it has been possible to make closer measurements in capillary tubes than in larger tubes. It is, moreover, easier to differentiate the layer of white cells if the columns of cells are measured in capillary tubes.

Gram and Norgaard (1923) employed a capillary tube with heavy walls, 10 cm. in length and graduated in 200 intervals, with hirudin as anticoagulant. Later Rosahn (1931) devised a tube somewhat similar to that of Gram and Norgaard and used heparin as the anticoagulant. In both procedures the tubes were sealed with rubber bands for centrifuging.

In several methods employing capillary tubes the use of rubber sealing devices has been avoided. Smirk (1929) used thin-walled capillary tubes of 0.3 mm. bore, bent into U-shape. Oxalated blood was drawn into such tubes with a layer of paraffin oil at each end of the column of blood to diminish the loss of  $\text{CO}_2$ , and the tubes were centrifuged at 3,000 to 4,000 r.p.m. until the cells were packed to constant volume. The lengths of the columns of cells and plasma were then marked on paper by pricking points, the distances between the points measured with dividers, and the cell volume in percentage calculated from these measurements. The results from the two columns of the U-tube were averaged. Smirk claimed that, at the same speed of rotation, more complete separation of plasma from cells was obtained by centrifugation in capillary tubes than in larger tubes, and that separation was more complete in shorter columns of blood, 5 to 6 cm., than in longer columns. Bönniger (1909) also had employed a U-shaped tube. Campbell (1922) used thin-walled capillary tubes which were partly filled with oxalated blood by dipping one end into the blood, and the opposite end then sealed in a flame. After centrifugation the lengths of the columns of cells and plasma were measured by a millimeter scale and the

percentage cell volume calculated. Epstein (1915) used heavier capillary tubes, of 0.5 to 1.0 mm. bore, with one end drawn out to be sealed in a flame. He placed granules of heparin in the tube and used blood obtained by skin puncture. After the tube was partly filled with blood and the small end sealed, the blood column was measured end to end and the thin end of the tube inserted into a cork for centrifugation. After centrifugation the length of the column of plasma was measured, the plasma volume was calculated in percentage and the volume of cells obtained by difference.

The method for the determination of the relative volume of cells in blood which is to be described here has been developed after a considerable amount of experimental work with many of the reported centrifuge methods; and various steps in the procedure have been adopted, with modifications, from a number of different sources. Briefly: in this method thin-walled capillary tubes in pairs are partly filled with heparinized blood, one end sealed in a flame, and the tubes thus filled are centrifuged until the cells are packed to constant volume. The columns of cells and plasma are then measured by means of a measuring microscope, and from these measurements the volume of "total" cells and "R.B.C." are calculated in percentage of whole blood. A high speed centrifuge with special head and a special measuring microscope are recommended, but practically identical results may be obtained with the ordinary types of laboratory centrifuge and microscope if the latter be equipped with a cross-hair eyepiece and a graduated mechanical stage. The principal advantages of the method are that it is economical of blood; that the anticoagulant used apparently does not affect the size of the cells; that the volumes of red cells and white cells may be read separately with ease; that errors due to rubber sealing devices are avoided; that it is rapid.

#### APPARATUS

Vials to receive the blood samples may be prepared, a large number at a time, by placing in small vials appropriate amounts of a 1 per cent solution of heparin\* in distilled water. Convenient sizes are 2 c.c. or 4 c.c. vials which receive respectively 0.1 or 0.2 c.c. of this solution; i.e., 1.0 or 2.0 mg. of heparin. The water is then evaporated from the vials in a drying oven at 100° C., or in a vacuum oven at a lower temperature. In either case the vials should not be left in the oven longer than necessary, because after prolonged heating the heparin tends to dissolve in the blood less readily. When dry, a glass bead and a closely fitting rubber stopper are placed in each vial.

*Capillary tubes* are prepared from ordinary soft glass tubing (internal diameter 10 mm. and wall 1.0 mm. in thickness) which has been cleansed with acid cleaning mixture, rinsed with distilled water and dried. This tubing is heated over a Bunsen burner with wing top adjusted to give as even a flame as possible, and the heated portion is drawn out 15 or 20 feet by two people walking rapidly away from each other. The pulled capillary tube should be held taut until well cooled, and then dropped onto a flat surface in order to

\*The heparin is obtainable from Hynson, Westcott and Dunning, Baltimore. Several writers have suggested the advantages of the use of heparin in cell volume studies, but dismissed it as too expensive. The use of small blood samples reduces the cost, and in this method of drying there is little waste.

minimize its tendency to warp into curves. From this capillary tubing 12.0 cm. lengths are cut and carefully selected for straightness and absence of taper. Such selection may be made conveniently by rolling the capillaries on a flat surface (plate glass) which is slanted a few degrees. The curved tubes are culled out by their failure to roll, and a significant degree of taper will cause the tubes to roll to one side. The most suitable capillary tubes may range in internal diameter from 0.4 to 0.8 mm., with walls 0.1 to 0.15 in thickness. In our experience the yield of acceptable tubes prepared in this fashion is from 20 to 40 per cent. Because the heat employed in drawing the tubing may cause some alkali to appear on the surface of the glass, the selected capillaries should be dropped into acid, rinsed with water and dried. Such rinsing is easily done by placing a number of the capillary tubes in a glass cylinder or test tube which is filled and emptied several times in succession with acid, distilled water, alcohol, and ether. After the final washing with ether, the capillaries may be placed in a drying oven for a short time to drive out the ether.

Fig. 1.—Centrifuge head used with the high speed attachment of the International centrifuge.

The labor involved in preparing the capillary tubes is somewhat compensated by the fact that the tubes when used once are thrown away, and no time is spent cleaning them.

*Centrifuge.*—The special head shown in Fig. 1 may be used for centrifuging the capillary tubes on the high speed attachment of the International centrifuge.\* This head has a radius of 75 mm., and has places for eight small metal cylinders, each bored to carry a pair of 6 cm. capillary glass tubes. The tubes are carried horizontally, in their plane of motion, so that at the end of centrifuging the tops of the columns of packed cells are level. With this head the best results have been obtained by a speed of 14,000 r.p.m. for from four to five minutes. An automatic timing device to stop the centrifuge is helpful.

For centrifuging in the usual style cups with an ordinary type of centrifuge capable of speed around 3,000 r.p.m., carriers for the capillary tubes can be made from a block of wood or aluminum made to fit loosely in a centrifuge cup and bored with small holes, each hole just large enough to carry a pair of the capillary tubes. Several pairs can be carried in one such block.

\*The International Equipment Co., Boston, Mass.

*Measuring Microscopes.*—In all the control studies listed here the measurements of the columns of blood cells and plasma after centrifuging were made by means of the measuring microscope shown in Fig. 2.\* The positions of the microscope, the light source, etc., as shown in the figure, are arranged for the comfort of the operator. Two pieces of opaque paper are pasted on a plate of glass so as to make a horizontal narrow slit in which the capillary tube is placed for the measurements. The light is reflected from a mirror through the slit, and readings are made by transmitted light which makes the line of demarcation between white and red cells more distinct. While this microscope permits readings to 0.01 mm., any laboratory microscope (low power objective) equipped with a cross-hair eyepiece and a graduated mechanical stage with vernier which permits readings to 0.1 mm. gives results practically identical

Fig. 2.—The measuring microscope, arranged for measuring the lengths of columns of blood cells and plasma.

with those obtained by closer readings. For use with the ordinary microscope, a holder for the capillary tubes may be made by pasting two pieces of opaque paper on a glass slide so as to make a narrow slit in which the capillary tube is placed during its measurement. Light is reflected through this slit from below by the mirror of the microscope substage.

#### METHODS

The blood sample for the cell volume determination should be obtained with a dry syringe and needle and quickly mixed with the heparin, 2 c.c. of blood to 1.0 mg. of the anticoagulant, in a small vial such as previously described. Care should be observed to avoid air bubbles in the blood discharged into the vial, and mixing of the anticoagulant should be by gentle inversion of

\*Obtained from the Central Scientific Company, Chicago, Illinois.

the tube without violent shaking which is likely to produce foaming. If tissue juices are mixed with the blood, or if slight clotting of the blood starts in the syringe before it is discharged into the heparin vial the formation of particles of fibrin may cause difficulty even though the blood appears grossly to be unclotted. With slight fibrin formation the line of demarcation between the red and white cells is harder to read and sometimes the white cells are found scattered through the red cells, apparently caught in the strands of fibrin. The heparinized blood may be used also for cell counts, hemoglobin estimation and any other chemical examinations with which heparin does not interfere.

At the time of use one of the 12.0 cm. capillary tubes is cut in the middle to give a pair of tubes which are turned to bring their "outer" ends together. Several pairs (usually four in our own work) should be used for each blood sample. The "outer" ends of each pair of tubes are thrust deeply into the *well mixed* blood and filled by capillarity to within about 2.0 cm. of the "inner ends"—i.e., the ends that came from the middle of the original tube. Finally a layer of paraffin oil 2.0 to 3.0 mm. deep may be drawn into the tubes over the columns of blood. The oil serves mainly to prevent evaporation of water from the surface of the plasma; it is doubtful whether it diminishes the loss of  $\text{CO}_2$ , as claimed by Smirk who used it in a similar fashion. The oil is not essential to secure results sufficiently accurate for routine clinical work. The "inner" ends are then sealed by holding them perpendicular to and just touching the outer margin of a micro burner gas flame. With care and slow rotation the tube can be sealed quickly with a flat inner base. It is important that this be done carefully, since slight taper in the sealed base of the tube makes the final measurement of the lengths of the blood column less accurate. If the wall of the tube is too thick, or if the glass has not a low melting point, it is difficult to make such a seal quickly and the glass may become hot so far up the tube that there is danger of overheating the lower part of the blood column. This manner of sealing excludes the possibility of even slight loss of blood by leakage which is a frequent source of error in hematocrit tubes with rubber sealing devices. The advantage of having the pair of tubes cut from one longer tube, and turned as described, lies in the fact that the slight taper usually present even in the most carefully selected capillaries is then in the opposite direction in each tube of the pair, and, therefore, the error due to taper in the one compensates that of the other in the final results.

The tubes thus filled and sealed are centrifuged, either in the special head (Fig. 1) at approximately 14,000 r.p.m. for from four to five minutes, or in the ordinary centrifuge at approximately 3,000 for thirty minutes. In samples of dog's blood with red cell counts as high as eight million or more, the period of centrifuging at 14,000 r.p.m. should be extended to five or six minutes. With slower speeds a longer time is necessary to completely pack the cells; with speeds higher than 14,000 r.p.m. the red cells in some blood samples tend to rupture and the hemoglobin becomes diffused into the layer of white cells, making the line of demarcation between the red and white cells harder to read. After centrifuging, the capillary tubes are immediately placed upright in a block of wood bored with small holes to receive them; if left lying horizontally for more than a few minutes the top of the layer of cells will be slanted.

For the measurements, each capillary tube is placed in the light slit of the glass slide before the measuring microscope. With the stage of the latter set at zero, the capillary tube is adjusted by hand to bring the base of the blood column to the cross-hair of the eyepiece; the stage is then moved laterally and readings are made at the line of demarcation between the red and white cells, at the top of the white cells and at the meniscus of the plasma. From these measurements on each tube the cell volumes, "R.B.C." and "Total," are calculated in percentage of whole blood. The values for each pair of tubes are averaged (as shown in Table I), and as a rule the maximum variations between these averages in a set of four pairs of tubes is less than 0.4 per cent.

#### CONTROL STUDIES

*Internal Diameter of the Capillary Tubes.*—Two sets of capillary tubes were selected, the capillaries in each set having internal diameters 0.3 to 0.4 mm. and 0.6 to 0.8 mm., respectively. Six pairs in each set were filled alike, sealed in a flame as described and centrifuged at 12,000 r.p.m. for four minutes. The averages for the total cell volumes calculated for the two sets of tubes were respectively 45.41 and 45.39 per cent. Although there was found no significant difference between the results from the two sets, practically the tubes with internal diameters from 0.5 to 0.7 mm. are the most satisfactory to use. The smaller ones are too fragile; while the larger ones are harder to seal with a good flat inner base, and the thicker blood column makes the line of demarcation between the white and red cells harder to read by transmitted light.

*The Effect of Taper in the Capillary Tubes (Table I).*—It was previously stated that the reason for having the pair of capillary tubes cut from one longer tube is that they may be turned so that if slight taper is present, it will be in the opposite direction in each tube of the pair and the error due to taper in one will compensate that of the other. This effect is illustrated in Table I by the readings of a set of tubes in which the differences are considerable between the members of each pair and yet the agreement is good between the averages of the separate pairs.

TABLE I  
EFFECT OF TAPER IN THE CAPILLARY TUBES

| READINGS IN MILLIMETERS |        |        | CALCULATED CELL VOLUMES IN PER CENT |                    |       |                    |

| 23.11                   | 23.58  | 50.97  | 45.34                               |                    | 46.26 |                    |
| 25.43                   | 25.97  | 52.96  | 48.02                               | 46.68              | 49.04 | 47.65              |
| 23.65                   | 24.13  | 51.22  | 46.17                               |                    | 47.11 |                    |
| 24.50                   | 24.99  | 51.85  | 47.25                               | 46.71              | 48.20 | 47.66              |
| 24.53                   | 25.16  | 52.10  | 46.81                               |                    | 48.02 |                    |
| 23.99                   | 24.59  | 51.41  | 46.66                               | 46.74              | 47.83 | 47.93              |
| General Average         |        |        |                                     | 46.7               |       | 47.8               |

*Length of the Columns of Blood (Table II).*—Pairs of capillary tubes, 6 cm. in length and from 0.4 to 0.6 mm. in internal diameter, were filled with heparinized blood sufficiently to give blood columns ranging from 20 to 55 mm. in total length. These were sealed in a flame as usual and centrifuged at 12,000 r.p.m. for four and one-half minutes. The results listed in Table II indicate that the length of the columns of blood within these limits affects the final results very little.

TABLE II  
EFFECT OF LENGTH OF BLOOD COLUMNS

| LENGTH OF<br>BLOOD COLUMNS<br>MM. | NUMBER OF<br>PAIRS | CELL VOLUMES IN PER CENT |                |
|-----------------------------------|--------------------|--------------------------|----------------|
|                                   |                    | R.B.C.                   | TOTAL          |
| 20-29.9                           | 7                  | 45.63                    | 46.53          |

| Mean                              |                    | 45.70 ± 0.03             | 46.51 ± 0.02   |
| Standard Deviation                |                    | ± 0.18 ± 0.02            | ± 0.16 ± 0.02  |
| Coefficient of Variation          |                    | ± 0.38% ± 0.04           | ± 0.35% ± 0.03 |

*Time of Centrifuging at 14,000 r.p.m. Within a 7.5 cm. Radius (Table III).*—From a sample of heparinized normal human blood, 7 sets of capillary tubes, 4 pairs in each set, were filled and sealed as described. These sets in turn were centrifuged in the special head at 14,000 r.p.m. for periods from one-half minute to ten minutes. During the one-half minute period high speed was not attained. The results shown in Table III indicate that at 14,000 r.p.m., four to five minutes is sufficient to obtain constant packing of the cells in human blood. In this centrifuge, run at this speed, periods longer than ten minutes were undesirable because if run a longer time the apparatus tended to become heated.

It may be noted here that in the capillary tubes translucency of the blood cell column (Koeppé's criterion [1905]) cannot be accepted by itself as a criterion of complete packing of the cells; a fair degree of translucency sometimes may be observed before the cells are completely reduced to constant volume. The conditions of speed and time must be adjusted to obtain this maximum packing of the cells (without rupture of the cells), but on the other hand too long periods of centrifuging should be avoided because of chemical changes which may occur in the cells and alter their volume.

TABLE III  
TIME OF CENTRIFUGING AT 14,000 R.P.M.

| TIME<br>MINUTES | CELL VOLUMES IN PER CENT |       |
|-----------------|--------------------------|-------|
|                 | R.B.C.                   | TOTAL |
| ½               | 61.88                    | 62.75 |
| 1               | 48.15                    | 49.01 |
| 2               | 46.85                    | 47.59 |
| 3               | 46.50                    | 47.27 |
| 4               | 46.45                    | 47.31 |
| 6               | 46.44                    | 47.26 |
| 10              | 46.51                    | 47.25 |

*Time of Centrifuging at 3,000 r.p.m., Within a 20 cm. Radius.*—From a sample of heparinized normal human blood 5 sets of capillary tubes, 4 pairs in each set, were filled and sealed as described. Four sets were centrifuged in a 50 c.c. cup and holder, such as described under apparatus, with a No. 1 International centrifuge (Type SB) using a head with 15 cm. radius (the bottom of the cup traveled at a 20 cm. radius). When these 4 sets were centrifuged at 3,000 r.p.m. for fifteen, thirty, forty-five, and sixty minutes, the average total cell volumes measured in these sets were respectively 44.4, 44.2, 44.0, and 44.2 per cent. In the fifth set, centrifuged in the special head at 14,000 r.p.m. for four minutes, the total cell volume was 44.1 per cent.

In ordinary practice, therefore, centrifuging the capillary tubes to constant cell volume in the ordinary laboratory centrifuge should usually give results as satisfactory as those obtained with the special high speed centrifuge. In certain pathologic conditions, however, there is need to handle blood samples as quickly as possible after the blood is drawn, because rapidly progressing intracellular chemical changes may alter the size of the cells. For example, in certain types of severe acidosis and in gastroenteric intoxication of infants, it may be observed that glycolysis, lactic acid formation and liberation of inorganic phosphates by intracellular hydrolysis of organic phosphorus compounds occur more rapidly than in normal bloods (Guest [1932]). In circumstances such as these, the shorter period of centrifugation at higher speed is advantageous.

*Effect of Standing at Room Temperature (Table IV).*—Heparinized normal human blood was allowed to stand at room temperature (28° to 32° C.; this experiment being done in the summer) for seventeen hours. At intervals after the blood was drawn, indicated in Table IV, sets of four pairs of capillary tubes were filled, sealed, and centrifuged at 13,500 r.p.m. for four and one-half minutes. The results listed in Table IV indicate that in the first three hours there was a noteworthy shrinkage in the cell volume; part of this effect may be due to loss of CO<sub>2</sub> from the blood, and part to changes concomitant with glycolysis. In the later periods the increased amount of lactic acid accumulating as a result of glycolysis may be responsible for the swelling of the cells.

TABLE IV  
THE EFFECT OF STANDING, AT ROOM TEMPERATURE

| TIME AFTER BLOOD<br>WAS DRAWN | CELL VOLUMES IN PER CENT |       |
|-------------------------------|--------------------------|-------|
|                               | R.B.C.                   | TOTAL |
| 15 minutes                    | 45.8                     | 46.4  |
| 1½ hour                       | 45.4                     | 46.2  |
| 3 hours                       | 44.6                     | 45.4  |
| 6 hours                       | 45.1                     | 45.8  |
| 11 hours                      | 46.2                     | 47.0  |
| 17 hours                      | 46.8                     | 47.5  |

*Anticoagulants (Table V).*—A sample of normal human blood was drawn and delivered in 5 c.c. samples into small vials containing the following: (1) heparin 2.0 mg., (2) hirudin 2.0 mg., (3) sodium citrate 0.015 gm., (4) sodium oxa-

late 0.015 gm., (5) sodium fluoride 0.015 gm. Another sample, No. 6, was defibrinated with a glass rod. Four pairs of capillary tubes were prepared from each of these samples and centrifuged as usual. The results of the test are listed in Table V. It may be noted that identical results were obtained with the use of heparin and hirudin.

TABLE V  
EFFECT OF DIFFERENT ANTICOAGULANTS

| ANTICOAGULANT   |       | CELL VOLUMES IN PER CENT |       |
|-----------------|-------|--------------------------|-------|
|                 |       | R.B.C.                   | TOTAL |
| Heparin         | 0.04% | 45.1                     | 45.8  |
| Hirudin         | 0.04% | 45.1                     | 45.8  |
| Sodium citrate  | 0.3 % | 41.7                     | 42.4  |
| Sodium oxalate  | 0.3 % | 39.5                     | 40.0  |
| Sodium fluoride | 0.3 % | 36.3                     | 36.8  |
| Defibrinated    | -     | 44.8                     | 45.3  |

*Amount of Heparin.*—A sample of normal human blood was added to heparin in two vials in the proportion 0.5 mg. per c.c. and 2.0 mg. per c.c., respectively. Eight pairs of capillary tubes were filled from each vial and centrifuged at 14,000 r.p.m. for four minutes. The mean values for total cell volume in the two sets were respectively  $41.92 \pm 0.11$  and  $41.84 \pm 0.11$  per cent; two values with no significant difference by mathematical test. It may be assumed, therefore, that between these limits the proportion of heparin added to blood need not be accurately measured.

*Types of Glass Used in the Capillary Tubes.*—Because it is easier to draw capillary tubing from lead glass and to obtain a high yield of straight capillary tubes, it was hoped that this type of glass could be used. However, when sets of lead glass and soda lime glass capillary tubes were used for the same blood samples, the lead glass tubes gave results for cell volume about 2 volumes per cent lower than those obtained with the soda lime glass tubes. When these capillary tubes were kept for twenty-four hours after the determinations, it was observed that the packed cells in the lead glass capillary tubes become increasingly opaque, whereas, in the soda lime glass tubes the column of cells remained translucent. It seems likely that the lower cell volume was due to the effect of lead entering the blood from the glass. Pyrex glass is much more difficult to draw into capillary tubing sufficiently uniform for the needs of this method, and it is more difficult to seal Pyrex glass capillaries properly without overheating the blood in the tube.

*Comparison of Cell Volume Determinations by Other Methods.*—Twenty-five cubic centimeters of blood were drawn from a normal human adult and this sample divided for cell volume measurements according to four different methods: (1) The Sanford-Magath (1929) modification of the Haden method, (2) Van Allen method (1925), (3) Wintrobe (1929) method, (4) the capillary tube method as here described. Results averaged for several tubes used in each of these methods were respectively 45.4, 45.1, 47.9, and 47.3 per cent for the total cell volumes.

Studies of blood cell volume and erythrocyte size in arterial and venous blood, the effects of contact of the blood with air and changes in  $\text{CO}_2$  content,

and the effects of stasis of blood in veins before blood samples are drawn, will be reported in a later communication. It may be stated here, however, that when blood samples are handled as described in the foregoing pages, the slight losses of  $\text{CO}_2$  which may result from brief contact of the blood with air have practically no effect upon the cell volume.

## SUMMARY

A method for the determination of the percentage volume of cells in blood has been presented. Small capillary glass tubes in pairs are partly filled with heparinized blood, the tubes sealed in a flame, and the tubes then centrifuged until the cells are packed to constant volume, preferably at 14,000 r.p.m. for from four to five minutes in a special centrifuge head. The lengths of the columns of cells and of plasma are read either by a special measuring microscope or by means of an ordinary microscope equipped with a graduated mechanical stage. The readings are made to the top of the red cells, to the top of the white cells, and to the top of the plasma. From these measurements the relative cell volumes "R.B.C." and "Total" are calculated in percentage of whole blood. Control studies are presented to indicate the accuracy and variations to be expected in measurements made by this method.

## A PRACTICAL METHOD FOR THE CONTINUOUS ADMINISTRATION OF FLUID INTRAVENOUSLY\*

HENRY R. JACOBS, M.D., CHICAGO, ILL.

WHEN the intravenous administration of liquid is desirable, an efficient apparatus designed to perform this service is welcome. Such an apparatus must accomplish its function with safety and dependability, as well as provide for the comfort of the recipient, if it is to compete with other methods.

The apparatus here described was designed specifically for the intravenous administration of liquids at constant rates for long periods of time. Its primary purpose is to deliver liquid into the veins of sick patients under conditions determined by them, meanwhile satisfying the requirements of asepsis, of safety, of dependability, and of ease of manipulation.

Although it will probably find its greatest uses clinically in those cases requiring long treatment, this apparatus is also well adapted for use in cases where no cooperation is offered by the recipient. In the laboratory, when mounted on a rotating platform on top of a cage, it becomes an efficient instrument for the continuous intravenous injection of animals.

The apparatus, which is shown in the photograph (Fig. 1), consists of (1) an eccentric rotor driven by a variable-speed synchronous type motor, and (2) an independent tube for conducting the liquid. The pump itself operates on the well-known principle of "milking a tube," modified to avoid all connection between pumping mechanism and conducting system. A powerful propulsion of liquid is effected by the progression of the eccentric rotor over a spiral segment of the conducting tube. The rest of the apparatus embodies several other principles which guarantee the uninterrupted injection of sterile liquid even without the cooperation of the recipient.

In order to assure a smooth and uninterrupted one-way flow, the liquid is carried under pressure to the point of discharge, and is there released to flow freely into the vein. This operation is achieved through use of a release valve at the end of the conducting tube which not only offers resistance to the forward flow, but also prevents the backward flow of liquid. The valve consists of a small piece of rubber tube which expands against a hole through which the fluid must pass. By this means the uniformity of flow is not affected by the swinging, stretching, or other manipulation of the conducting tube.

The asepsis of the injection procedure is maintained by a completely closed system, entirely independent from the pumping mechanism. This closed system

\*Received for publication, May 16, 1933.

is sterilizable in the autoclave, since it consists of a single tube from beginning to end without connections of any kind.

The recipient is relieved of the duty of keeping his arm in one position by a combination of three features. The first has already been mentioned: liquid will be discharged uniformly in spite of all manipulations of the conducting tube. The second is that the tube is so firmly anchored to the arm by a substantial arm plate (Fig. 3) that it cannot be dislodged. The third is that the

Fig. 1.—Photograph of the complete apparatus.

Fig. 2.—Sketch of the mechanism.

liquid is injected into the vein through a fine rubber capillary tube which is so flexible that no movements of the arm can affect its position within the vein. Not only may the recipient move his arm as he pleases, but also is only little disturbed by the capillary tube in his vein.

When the injection is prolonged and the exchange of supply flasks frequent, a connection such as that shown in Fig. 1 is useful. It consists of a glass tube to withdraw the liquid and a sealed-on glass skirt to enclose the neck of the flask. This connection insures sterility, facilitates refilling, and permits the flasks to stand upright.

If the operator wishes that a signal be given when the supply flask has been emptied to a certain level, he may set the flask upon one pan of a balance which

has a counterpoise on the other pan representing the weight of the flask when it has been emptied to this level. Further withdrawal of liquid will then cause the balance to swing and close an electric circuit containing a suitable signal. He may also interpose a trap in the conducting tube to catch air and sediment and to indicate the rate of flow.

The technic used to operate this apparatus is as follows: After sterilization, the conducting tube is attached to the machine and the machine set in motion. When all the air has been driven out of the tube and liquid has begun to flow regularly from the release valve, an intravenous needle (Size 15) is placed in

Fig. 3.—Photograph of arm of recipient with apparatus attached.

Fig. 4.—Photograph of a "threaded" syringe.

the vein. The capillary rubber tube is injected through the needle from a syringe (Fig. 3). The knot in the proximal end of the capillary tube, which was placed there to catch at the shoulder of the syringe, is cut off after the syringe has been detached, and then the needle is withdrawn. The capillary tube is attached to the release valve through a fine Luer needle. The release valve is attached to the arm plate after the latter has been taped to the arm. A small dressing is placed over the puncture wound through which the tube passes. The injection may then be continued indefinitely, the recipient meanwhile having the liberty to move his arm as he pleases. The rate of injection may be changed by the ratios of 1:2:4 by turning a switch. The present machine delivers liquid at the rates of 75, 150, and 300 c.c. an hour. Rates outside these limits require the use of tubes of suitable size.

Because the discharge into the vein is slow and constant the liquid need not be warmed. For the same reason hypertonic solutions of glucose (in normal salt solution) may be injected safely.

The several mechanical features in this apparatus which contribute to its successful performance are the following: The driving mechanism is completely enclosed and will run indefinitely without attention. The pump will develop enough pressure to burst the tube, yet the wear on the tube by the rotor is negligible. The release valve is made of stainless steel and furnishes, through connection to the arm plate, absolute anchorage. All parts susceptible to deterioration, namely, the conducting tube, the rubber capillary tube, and the tube in the release valve, are readily and cheaply replaceable. Clotting within the capillary tube is impossible, because blood has no opportunity to enter it, since liquid is continuously flowing out. A smooth and uniform discharge from the capillary tube is guaranteed by a balance of two forces, the cushioned liquid pressure within the conducting tube and the resistance of the release valve. The rubber capillary tube, which was developed especially for this work, has an outside diameter of 0.04 inch. It is made of high grade anode rubber, and it will retain its elasticity and tensile strength through many days of contact with blood.

The Oak Manufacturing Company, Chicago, Illinois, kindly undertook to make this machine.

## THE STABILITY OF DIOTHANE SOLUTIONS\*

T. H. RIDER, PH.D., CINCINNATI, OHIO

---

ATTENTION has already<sup>1</sup> been called to the unusual behavior of some phenyl urethane local anesthetics when their solutions are boiled. The monophenyl urethanes of di-n-butyl- and di-iso-butyl-amino propanediols were found to be altered by boiling their solutions in such a way that their activity as surface anesthetics materially increased while the anesthesia produced by their intradermal injection was shortened. This was interpreted as being due to some change of an unknown nature which resulted in the creation of a more rapidly diffusible form of anesthetic.

When diothane (piperidinopropanediol di-phenyl urethane hydrochloride) was selected as a new and valuable anesthetic for clinical trial, the behavior of its solutions on heating was checked, and it was found and reported that sterilization over prolonged periods did not alter the solution according to physiologic tests.<sup>2</sup>

A further detailed chemical study of diothane and its solutions has revealed the fact that the anesthetic free base is relatively unstable to heat. Heat-

---

\*From the Research Laboratories of The Wm. S. Merrell Company.  
Received for publication, May 23, 1932.

ing this free base to its decomposition point in a vacuum has yielded traces of aniline together with other unknown decomposition products. The crystalline hydrochloride is quite stable to moderate heat (100° C.) when the crystals are dry, but somewhat unstable to heat when they are wet with water or other solvent capable of partially dissolving them. The amount of change is too slight to allow the isolation of any decomposition products.

Since the wet crystals proved to be somewhat unstable it was deemed advisable to restudy the stability of diothane solutions.

The treatment of local anesthetic solutions with dilute nitrous acid followed by the addition of an alkaline solution of beta-naphthol is a recognized test for distinguishing those products containing primary amino groups. Thus procaine gives a dark brick-red precipitate (positive) while cocaine gives a yellow-white precipitate (negative). Freshly prepared solutions of pure diothane crystals give a typical negative reaction. However, when these solutions are heated for prolonged periods (> one hr. at 98° C.) or aged for many months, diazotization and coupling with beta-naphthol gives a light orange precipitate.

This change as attested by the delicate chemical reaction is accompanied by no demonstrable change in anesthetic activity or toxicity of the solution, indicating that the extent of any change is extremely slight.

Theoretical consideration of possible changes which would result in the creation of diazotizable amino groups suggested only two reactions. The first of these was a possible rearrangement as follows:

Since this rearrangement would account for the formation of a colored dye in the test reaction, an attempt was made to determine the amount of change which would account for the degree of color actually developed. In order to check this point to some extent diothane solutions were made up containing various quantities of procaine, and these solutions were tested together with the oldest diothane solution available (two years). The colors developed by the solution containing procaine were quite different in shade, but the intensity of color developed by the old diothane solution was similar to that of a fresh diothane solution containing procaine 1:90,000. Similar tests were carried out by adding traces of the di-p-amino benzoate homologues of diothane, and since these products contain two primary amino groups per molecule even smaller proportions were required to give colors of the same intensity.

In this connection it is of interest that the di-p-amino benzoate of piperidinopropanediol<sup>3</sup> has almost no activity as a mucous membrane anesthetic. It is obvious, therefore, that if this product were found in diothane solutions in any quantity, the change would be detectable by physiologic tests.

Remembering that thermal decomposition of diothane free base had yielded traces of aniline, diothane solutions with added quantities of aniline hydrochloride were also tested in comparison with the oldest diothane solution. Again the shade of color developed in the test was somewhat different, but an even closer comparison of intensities was possible. In this case, the intensity de-

veloped with the old diothane solution was most closely matched by that with a fresh diothane solution to which aniline had been added in a concentration of 1:200,000.

In both cases the color developed by the diothane solution, to which the primary amino compounds had been added, was concentrated on the otherwise yellow-white precipitate, making the very slight color formation quite obvious. In neither case was there similarity enough in the shade of color to indicate that either an amino benzoate or aniline had actually been formed. These experiments indicate, however, that an extremely small proportion of the diothane had been altered.

While in the above discussion the two-year-old diothane solution was specifically mentioned, the same alteration of the solution may be rapidly achieved by heating the solution for several hours on a steam-bath. The addition of a slight excess of acid to the solution markedly delays such changes as take place, and no significant change occurs during the first hour of heating, so that solutions may be adequately sterilized without alteration.

Attempts to correlate the changes in diothane solutions with the increased surface activity of the di-n-butyl- and di-iso-butyl-amino propanediol mono-phenyl urethane solutions have not been productive, since these boiled solutions do not yield any colored product on attempted diazotization and coupling with beta naphthol.

#### SUMMARY

Prolonged heating or aging of diothane solutions produces a very slight degree of alteration detectable by delicate colorimetric testing, but not detectable by pharmacologic methods. Theoretical considerations of possible changes have been discussed, and it has been inferentially shown that the concentration of any alteration product in diothane solutions is probably not greater than 1:100,000.

The writer wishes to acknowledge the assistance of Dr. E. W. Scott and Messrs. A. R. Lux and Karl Bambach.

## THE PRESERVATION OF BIOLOGIC SPECIMENS\*

GRACE I. DAVIS, B.S., AND THOMAS W. DAVIS, PH.D., NEW YORK, N. Y.

**T**ISSUES which are to be preserved for study or exhibit are often fixed by means of a formalin solution, and then kept immersed in an aqueous solution of sodium acetate containing glycerin and thymol. It is a common observation that the preserving media become clouded after a few weeks or months and must be replaced. To reduce the necessity for frequent replacement, we have undertaken a study of the cause of clouding, hoping to be able to control it by suitable means.

Our investigations have shown the turbidity, which seems not to be peculiar to any special kind of tissue although some specimens induce more rapid clouding than others, is due to oxidation of the thymol in the preserving fluid. While thymol is an inhibitor of bacterial growth, its solubility in water is low, and there seemed to be a possibility of bacterial changes causing precipitation in our solutions. This possibility has been definitely disproved as will be shown later.

### METHODS OF STUDY

In these studies, we have used the solutions already referred to. Tissues known by experience to have a tendency to cause clouding were fixed by soaking in a solution of the following composition: Chloral hydrate 500 gm., sodium chloride 180 gm., sodium bicarbonate 100 gm., sodium sulphate 220 gm., 40 per cent formalin solution 500 c.c., water to make 10,000 c.c. After the tissues had been hardened in this solution for several days, they were washed in running water for twenty-four hours, and then, after suitable mounting, kept immersed in a solution consisting of glycerine 2,000 c.c., sodium acetate 800 gm., thymol 100 gm., and water to make 10,000 c.c. The thymol was dissolved in boiling water, added to the main bulk of solution, and the whole cooled and filtered before using. Considerable excess thymol was removed in this step. Where special solutions were needed, they were made up in small amounts, and their use is reported below.

The tissues used for our controlled experiments were from a normal brain, and showed a marked tendency to induce clouding.

Since clouding of our media did not set in normally until six weeks or more after they had been prepared, we heated some of our specimens to a temperature of about 50° C., so that precipitation would be observed in a matter of days rather than weeks. The conclusions to be drawn from the experiments at the higher temperatures can with due allowance be applied to conditions at room temperature.

Received for publication, May 19, 1933.

## RESULTS AND INTERPRETATION

The first clue to the cause of clouding was found in the observation that all specimens led to turbidity, and that where it occurred the turbidity began after several weeks' standing and then increased slowly to a maximum. The white cloudiness seemed to be of the same character in all cases and resembled that noted when saturated thymol solutions are cooled.

It was thought that some obscure bacterial infection was the cause of the difficulty. Were there bacterial action operating, however, the clouding would probably develop quickly and continuously. In an endeavor to observe the actual organisms present, clouded fluid was examined under a microscope. It appeared perfectly clear. This indicates that the precipitate is very finely divided, but does not exclude the possibility of very small microorganisms being present. All efforts to culture the clouded media failed. Inoculation of a new sample of the preserving fluid with clouded material failed to accelerate the development of new cloudiness. These observations indicated the absence of bacterial factors in this phenomenon.

It became evident to us that some slow chemical change in the medium itself, perhaps influenced by material extracted from the biologic specimens, is responsible. Two simple observations convinced us that this is the case, and that the source of the clouding is the thymol in the preserving medium. First, a badly clouded solution in which a panophthalmia exhibit had been kept was clarified by repeated boiling with paper fibers, and filtration. It was returned to the original jar containing the specimen and showed no further precipitation over a period of four months. On adding thymol to this solution, slight clouding was noted after four weeks. Second, a sample of the usual medium alone showed a turbidity after standing in the laboratory for from six to eight weeks.

The precipitate, we noted, is insoluble in acid and alkali, but is quickly dissolved by ether. It is not coagulated by strong calcium chloride solution. This behavior conforms to the expected action of thymol or a thymol derivative. The precipitate, we noted further, always begins at the surface of the preserving solution, indicating oxidation as a possible factor. This was confirmed in the following way. A sample of the original medium was slightly diluted with water and kept at 50° C. A second sample was simultaneously diluted with hydrogen peroxide solution, and kept at the same temperature. The latter sample clouded in a few hours, the former did not. It appeared, therefore, that oxidation has some part in the phenomenon. The experiment was repeated at room temperature. The medium with peroxide clouded in four days, the control medium has remained clear for as many weeks.

To determine whether the biologic samples themselves contribute to this oxidation, we kept a sample of tissue under water at 50° C., for several days. Naturally there was considerable extraction of soluble material in this period. The water extract was filtered and added to some preserving medium. A precipitate developed in a matter of a few days, where otherwise, it would not. Some water soluble material from the tissues, therefore, must catalyze the formation of the observed precipitate. Whether there may be other reactions than oxidation of the thymol which contribute to the clouding, our experiments do not show. We believe, however, that this is likely.

## AN IMPROVED PRESERVING FLUID

While these observations have identified thymol as the cause of precipitation in our fluids, there remained the problem of finding an adequate substitute. Certainly replacement of the thymol seems called for. A tissue placed in preserving medium without thymol has remained indefinitely clear, but there is some danger of mould growth in an acetate solution not protected by a fungicide. We have found that a small amount of phenol or toluol added to the solution gives the desired protection. Such solutions have remained clear for a period of nearly six months.

We have tried other methods of preservation, most of which have proved unsatisfactory. A specimen kept under pure glycerin became rather badly discolored after a short time. A thin coating of collodion did not prevent clouding of one specimen, but a coating of varnish did. Had the collodion film been thick and air-dried more thoroughly, it would undoubtedly have further slowed up the clouding, but would not eventually preclude its appearance. The coating of varnish, likewise, does not offer permanent protection against clouding.

A layer of paraffin oil over the acetate preserving solution, by slowing up the admission of oxygen, inhibited but has not prevented clouding of the medium. When immersed in pure paraffin oil and maintained at 50° C. for several weeks, one specimen caused no clouding, but on cooling there was developed a heavy turbidity, which disappears on reheating. This probably is due to water which was distilled into the paraffin at the higher temperature, and which was thrown down by cooling. At constant temperature, however, there is no precipitate and if kept at room temperature, paraffin oil should be a satisfactory preserving medium. By actual test, we have found the oil with tissue immersed in it to remain clear for over three months. Substitution of magnesium sulphate in equivalent concentration for the sodium acetate does not greatly retard the formation of cloudiness; it had been thought that the higher ionic charge would decrease the formation of the colloidal suspension.

## SUMMARY AND CONCLUSIONS

1. An investigation of the media in which biologic specimens are preserved shows that the frequently observed clouding is due to a chemical oxidation and precipitation of thymol in the preserving fluid, catalyzed by materials extracted from the tissues.

2. An improved fluid in which phenol or toluol is substituted for thymol has proved satisfactory in practice.

3. Paraffin oil may be used as a preserving fluid, provided the temperature does not vary over too wide a range.

The assistance of Dr. M. J. Fein, pathologist of the Cumberland Hospital, in carrying out this work is acknowledged.

# CHANGES IN CELL VOLUME PRODUCED BY VARYING CONCENTRATIONS OF DIFFERENT ANTICOAGULANTS\*

V. G. HELLER, PH.D., AND HENRY PAUL, B.S., STILLWATER, OKLA.

A STUDY of the distribution of certain inorganic elements in cells and plasma reveals that the cell-plasma ratio varies not only with the nature of the anticoagulant but also with its concentration. Since the accuracy of such an investigation is dependent upon a definite cell volume as a basis for each calculation, the literature was investigated to ascertain the preferable method of procedure. Many substances are recommended as anticoagulants, the kinds, concentrations, and manner of use being almost as variable as the number of investigators. Definite lengths of time and speed of centrifuging, as a rule, are not stated. Guillaumin,<sup>1</sup> Eisenman,<sup>2</sup> and Hirota<sup>3</sup> all give some data pertaining to the subject in general but fail to furnish information applicable to this problem. In many cases, apparently, the manner of determining the cell volume was largely a matter of choice, so far as any definite method of procedure was concerned. For these reasons, it was deemed advisable to investigate the effects of the commonly recommended anticoagulants, and the conditions most suitable for determining the true cell volume.

## EXPERIMENTAL

Of the anticoagulants commonly recommended, the following have been employed in this investigation; sodium, potassium, and ammonium oxalates of concentrations 0.1 to 0.4 per cent by weight, the corresponding citrate salts of concentrations 0.2 to 0.8 per cent by weight, and heparin of concentrations 0.1 to 1 mg. per ml. of blood.

The cell volumes were determined using 4 mm. bore hematocrit tubes 15 cm. in length. The cell and serum heights in the tubes were measured with vernier calipers, thus eliminating the use of graduated tubes. The tubes were filled by means of capillary tubing; after which they were sealed and suspended on a rubber cushion in a position which would bring their axes perpendicular to the axis of rotation while centrifuging. A large size standard International Centrifuge was used, the speed being checked by use of a tachometer.

The time required at various speeds for the cell volume to become constant was ascertained. Determinations were made at two speeds—1800 and 2200 R.P.M. At lower speeds the time required was excessive, and it was difficult to prevent hemolysis; at higher speeds the tubes were frequently broken. The apparent cell volume was read at intervals during the centrifuging, and the data so obtained are presented in the accompanying chart. An examination of these curves reveals that in the case of cow's blood the cell volume becomes constant in 65 minutes at 1800 R.P.M. and in 45 minutes at

\*Received for publication, June 21, 1933.

2200 R.P.M. while for chicken blood, which contains larger cells, only 40 minutes at 1800 R.P.M. were required.

Using these standard conditions the cell volumes were determined with the various anticoagulants previously mentioned. Blood of cattle, chickens, and rats was drawn with an hypodermic needle, either from the jugular vein or by heart puncture, and delivered into flasks coated with the designated quantity of anticoagulant. After thorough mixing and chilling, the blood was delivered to the hematocrit tubes as described. The concentrations mentioned earlier in this article represent the extremes used by most investigators. These tests have been frequently repeated for various types of blood, and typical results are shown in Table I.

It will be observed from an inspection of the table that the ammonium salts produce an increase in cell volume with an increase in the percentage of

Chart 1

anticoagulant used, while sodium, potassium, and lithium salts produce a cell-volume decrease with percentage increase of salts used. Various determinations indicate that about 0.2 per cent of the oxalates and 0.4 per cent of the citrates produce the most favorable results from the standpoints of anticoagulation and hemolysis. Since ammonium salts produce an increase in cell volume and the other salts have an opposite effect, various mixtures have been tested, and it has been found that with the use of an 0.2 per cent concentration of a mixture of 40 per cent potassium oxalate and 60 per cent ammonium oxalate there is a minimum change in cell volume. These data are presented in Table II.

In the analysis for inorganic constituents, any inorganic anticoagulant interferes. Heparin was tried for this reason although it carries a calcium contamination. Its use is more difficult than that of the inorganic compounds as it does not dissolve as readily due to its dryness, and there is, consequently, a tendency to form small clots about the particles of heparin. It cannot be dissolved and evaporated over the surface of the container as it is an organic

compound, which might decompose on heating. The most satisfactory procedure consisted in making a water suspension, which caused the heparin to dissolve rapidly when added to the blood. Although the use of this compound as an anticoagulant has been repeatedly tried, it is impossible to secure results that check as favorably as those for the inorganic compounds. Table III presents the averages of two series of results from the experimental use of heparin to coagulate the blood of rats and of chickens. These data indicate

TABLE III

CELL VOLUME PRODUCED BY VARYING CONCENTRATIONS OF HEPARIN  
AS COMPARED TO POTASSIUM OXALATE

(MG. PER ML.)

| Chicken         | 27.00                                        | 26.19   | 26.19 | 26.16 | 26.37 |

that the concentration does not affect the ratio noticeably, but there is some cell packing with greater concentration. The cell volume is always slightly less than when inorganic anticoagulants are used.

#### CONCLUSIONS

1. There is a need for a specified concentration of anticoagulant as well as speed and time of centrifuging if cell-serum ratios are to be used in calculations.
2. Increasing concentrations of sodium, potassium, or lithium salts cause a decrease in cell volume.
3. Ammonium salts cause an increase in cell volume with increased concentration.
4. Within normal limits, a mixture of 40 per cent potassium oxalate and 60 per cent ammonium oxalate gives a minimum cell volume variation.
5. A speed of 2200 revolutions per minute was found most satisfactory, all factors being considered.

### THE KOLMER, KAHN, AND MEINICKE REACTIONS IN THE TROPICS\*

PAULINE BEREGOFF, M.D., CARTAGENA, COLOMBIA, S. A.

THE object of this study was to adopt for our laboratories a test which can be rapidly performed, is of highest sensitivity, is of greatest technical accuracy, and which is specific in its reaction, uniform in results, and also simple and economical.

#### MATERIAL

1. Serums from 700 syphilitic cases included primary, secondary, and tertiary congenital and latent syphilis. One-third of the cases presented secondary syphilis. Most of the patients were untreated.

2. Serums of 300 nonsyphilitic controls were obtained from 100 patients with severe secondary anemia due to intestinal parasites; from fifty cases of acute malarial fever; from fifty cases of chronic malaria; from twenty-five cases of mycotic disease of the skin; from 10 lepra cases; fifteen frambesias and fifty postoperative cases. None of these patients presented any symptoms or gave any history of syphilis. Careful observations were made on all cases; complete physical examinations and histories were taken in all.

## COMMENT

The Kolmer complement fixation test is harder to perform and less economical than the precipitation tests of Kahn and Meinicke, but the results obtained are of greater uniformity and give the lowest percentage of non-specific doubtful reactions. In our group of negative serums, we had not one nonspecific positive reaction with the Kolmer test. Even though it is a more complicated test to learn and harder for the technician to perform, yet once mastered, the test is much more easily interpreted than the precipitation tests. It gives clear negatives in every type of the tropical diseases in which we have used it, when there was no manifestation of syphilis involved. In the repeated tests of the same serums the Kolmer test gave the same reactions.

The Kahn test, though of greatest sensitivity, is less specific in reaction than the complement fixation test. However, the simplicity of the test and the rapidity with which it can be done recommend it for daily routine in the laboratories of tropical countries. The Kahn test is as hard to interpret as it is easy to perform. It requires skill and good eyesight to avoid false reactions. Doubtful reactions should always be repeated in conjunction with the complement fixation test. This test is of great value in emergencies as an immediate aid in the diagnosis.

The Meinicke test is less sensitive than the Kahn and gives the greatest percentage of nonspecific positive reactions in our group. It is very easy to perform and the interpretation, when delayed for several hours, is much easier

than in the Kahn test. When read immediately, the same difficulties are met. Our technicians prefer the Meinicke test to other precipitation tests because of the easier interpretation.

In all laboratories the precipitation tests should be always performed in conjunction with the complement fixation test. In the tropics, a precipitation test is of great value because of the rapidity with which it can be performed. The climate tends to decompose the blood very rapidly, and often it is necessary to perform the test as soon as specimens reach the laboratory. All doubtful and suspected positive reactions are always repeated in conjunction with the complement fixation tests. For specificity, we depend on the Kolmer test.

#### CONCLUSIONS

1. One thousand serums have been studied by the Kolmer, Kahn and Meinicke reactions; 700 serums were from known syphilitic cases, and 300 were negative controls.

2. The precipitation tests were found most sensitive, but less specific than the complement fixation test.

3. The precipitation tests are less complicated to perform and more economical, but they are harder to interpret than the complement fixation test.

4. The precipitation tests are readily adaptable in routine laboratory procedure; because of the rapidity with which the test may be performed, it is of value in emergencies.

5. The Kolmer complement fixation test is more complicated to perform, but easiest to interpret. It is most specific in reaction.

6. The precipitation tests should always be used in conjunction with the complement fixation test, except in emergency cases.

I am grateful to Dr. Kolmer and Dr. Kahn for supplying me with antigens for this study.

# NOTE ON THE DETERMINATION OF BLOOD UREA BY DIRECT NESSLERIZATION OF A SODIUM TUNGSTATE—SULPHO- SALICYLIC ACID FILTRATE\*

DONALD F. EVELETH, PH.D., AMES, IOWA

THERE are several methods of determining urea by direct nesslerization of a protein-free or nearly protein-free blood filtrate. Karr,<sup>2</sup> Roe and Irish,<sup>5</sup> Myers,<sup>4</sup> and Looney<sup>3</sup> all have described methods based on the nesslerization of a Folin and Wu<sup>1</sup> tungstic acid filtrate of blood. None of these methods has been entirely satisfactory for routine procedures. The aeration method of Myers<sup>4</sup> is simple and, if relatively large numbers of determinations are being run simultaneously, is very satisfactory. If only an occasional urea determination is made, or if speed is of importance, either the aeration method or the distillation method requires too much time.

Woodward and Fry<sup>6</sup> have recently used sulphosalicylic acid for the preparation of an acid, protein-free blood filtrate for the determination of blood glutathione. This reagent seemed to offer possibilities as a protein precipitant for the direct determination of urea in blood.

## EXPERIMENTAL

Woodward and Fry used one volume of an approximately molar solution of sulphosalicylic acid for the precipitation of the proteins of one volume of blood after dilution with eight volumes of water. They found that clear protein-free solutions could be obtained with human blood. In the experiments reported here, it has been found that some bloods, particularly swine blood, gave a brownish colored filtrate when sulphosalicylic acid alone was used. Other bloods usually gave clear, colorless filtrates. By including sodium tungstate in the precipitating mixture, the yield of filtrate was smaller but, with all bloods examined, a colorless filtrate was obtained. These filtrates were found to develop a brownish color when made alkaline to litmus. The further addition of alkali resulted in a perfectly clear, colorless solution. The amount of alkali in 2 ml. of a dilute solution of Bock-Benedict Nessler's reagent was found to discharge completely the brown color of 5 ml. of neutralized blood filtrate. Nesslerized solutions, with or without ammonia present, would remain clear for several hours.

### *Procedure for the Determination of Urea in Blood.—*

#### Solutions:

1 M sulphosalicylic acid; 25 gm. of sulphosalicylic acid in 100 ml. of solution (Woodward and Fry<sup>6</sup>).

10 per cent sodium tungstate solution (Folin and Wu<sup>1</sup>).

\*From the Department of Veterinary Research, Iowa State College.  
Received for publication June 27, 1933.

Urease solution of Folin and Wu mixed just before using with the activating phosphate solution in a ratio of 9:1.

Bock-Benedict Nessler's solution (Myers').

Nitrogen standard. 0.0472 gm.  $(\text{NH}_4)_2\text{SO}_4$  per liter, 5 ml. 0.5 mg.

Sodium hydroxide approximately  $2/3$  N.

Technic:

Two milliliters of oxalated blood (2-3 mg. of potassium oxalate per milliliter of blood) and 1 ml. of fresh urease solution are pipetted into a large test tube or a small Erlenmeyer flask, the contents mixed, and the container stoppered and placed in a water-bath at 50 degrees C. for fifteen minutes. To the tube is added 13 ml. of distilled water, 2 ml. of sodium tungstate solution and with constant agitation, 2 ml. of the sulphosalicylic acid solution. The material is then filtered through a fairly retentive filter paper.

Five milliliters of filtrate is pipetted into a 25-ml. graduate cylinder. If a high urea content is anticipated, 5 ml. or more of water may be added; otherwise 1 ml. of  $2/3$  N sodium hydroxide is pipetted into the solution followed immediately by 2 ml. of dilute Nessler's reagent. The solution may be diluted further to approach the color intensity of 0.5 mg. of ammonia nitrogen in the standard.

The calculation then is:

$$\frac{S}{R} \times 0.5 \times \frac{D}{100} \times \frac{100}{0.5}$$

TABLE I  
RECOVERY OF ADDED UREA

| SAMPLE      | MG. UREA N ADDED | MG. UREA N FOUND | PERCENTAGE RECOVERY |
|-------------|------------------|------------------|---------------------|
| 2 ml. blood | 0.000            | 0.107            | ----                |
| 2 ml. blood | 0.194            | 0.300            | 99.4                |
| 2 ml. blood | 0.388            | 0.500            | 101.3               |

TABLE II

COMPARISON OF THE SSA DIRECT AND AERATION METHODS OF DETERMINING UREA NITROGEN

| SAMPLE  | SPECIES | MG. PERCENTAGE N |      | PERCENTAGE DIFFERENCE |
|---------|---------|------------------|------|-----------------------|
|         |         | AERATION         | SSA  |                       |

*Effect of the Sodium Salt of Sulphosalicylic Acid on Nesslerized Solution.*—Two nitrogen standards containing 1 mg. N were prepared; to one was added a neutralized solution of 5 ml. of M sulphosalicylic acid. After nesslerization and dilution to 100 ml., the two solutions gave identical intensity of color in the colorimeter.

*Recovery of Added Urea.*—Aliquot portions of a blood sample were measured into tubes. Water was added to the control, and urea solution to the other two tubes in order to keep all volumes equal. The results are shown in Table I.

Blood urea nitrogen of various species of animals was determined by the direct method as described, and simultaneous determinations were made by the aeration method. These samples were obtained from different sources, and nothing is known regarding the health of the animals. The comparative data are shown in Table II.

#### DISCUSSION

In the precipitation of the proteins of blood and urease, it has been found necessary to use both sodium tungstate and sulphosalicylic acid in order to get a colorless filtrate satisfactory for nesslerization. The filtrate obtained by using sulphosalicylic acid only was sometimes very brown, having almost the color of a nesslerized solution. Although this color was discharged by making the solution decidedly alkaline, the use of the sulphosalicylic acid and sodium tungstate combination was found preferable.

The alkalinity of the final solution is very important. Too high a concentration of alkali results in a turbid solution. It would be satisfactory to add the sodium hydroxide to the Nessler solution provided that sufficient amounts of acid were also added to the standard. Satisfactory results have been obtained by adding the sodium hydroxide after the Nessler's solution, instead of before as previously stated.

Fowl blood does not lend itself to the determination of urea by this method. The blood is low in urea, and it is very difficult to obtain samples free of clots. Cloudy solutions, which may be due, at least in part, to the high concentration of oxalate necessary to prevent coagulation, have frequently resulted.

Woodward and Fry<sup>6</sup> state that too much oxalate prevents complete precipitation of proteins with sulphosalicylic acid. The same has been found for citrates and fluorides; however, the amounts generally used as anticoagulants cause no difficulties.

#### SUMMARY

A simple method for the direct determination of urea in blood has been described.

#### ADDENDUM

Because of unavoidable circumstances the paper of Taylor and Blair<sup>7</sup> was overlooked during the experimental work reported in the preceding paper. A few analyses have been made in comparing the two methods on pooled samples of swine blood. The results indicate that either method is satisfac-

tory provided that the colorimetric comparisons are made soon after nesslerization. Nesslerized solutions of the Folin-Wu filtrate frequently develop turbidity on standing for fifteen minutes or more. This turbidity does not develop in the nesslerized sodium tungstate sulphosalicylic acid filtrates. From the point of view of simplicity of preparation, the alcoholic urease is more easily prepared and is equally as effective as the concentrated urease in the volume of blood used for analysis.

## SIMPLIFYING THE MECHANICS OF BACTERIAL FILTRATION\*†

ROY F. FEEMSTER, M.D., DR. P.H., BOSTON, MASS.

NUMEROUS articles have appeared in medical and scientific periodicals upon various aspects of filters which remove bacteria from fluids. An extended bibliography is found at the end of a chapter by Mudd in Rivers' volume on Filterable Viruses.<sup>1</sup> The worker who uses filtration as a frequent and important procedure in his work must necessarily familiarize himself with this literature and will gather together many hints and suggestions in regard to the mechanics of the process. On the other hand, the worker who seldom uses filtration usually fails to take time to read so widely and often learns the technic by trial and error. Many times some slight error in the arrangement of the apparatus or some accident in the process of filtering the sample will make it necessary to repeat the operation before a sterile filtrate is obtained. Because of this fact it seemed worth while to put into print a brief discussion of the most frequent pitfalls of the procedure.

Although more convenient types of apparatus for certain purposes have been devised, such as that described by Mudd,<sup>2</sup> the most frequently used arrangement is filtration through a Berkefeld or Mandler candle, or a Seitz disc, into a flask with a side arm, and the suggestions given here will deal with that simple set-up.

\*From the Massachusetts Department of Public Health and the Harvard School of Public Health.

Received for publication, June 28, 1933.

†The laboratory facilities for carrying on an investigation involving filtration are being provided through the courtesy of Dr. W. G. Smillie.

One cause of difficulties often results from the attempt to filter without a manometer to determine the pressure. It is easy to exceed the critical pressure of the candle and draw bacteria through. A manometer is not expensive, and one like that illustrated in Fig. 1 (A) can usually be assembled in a laboratory without having to purchase anything except the mercury and perhaps a piece of tubing with a 1 mm. lumen. The principle of the manom-

FIG. 1

eter is very simple. It consists essentially of a glass tube standing in a bottle of mercury. Attached to the upper end of the tube is a piece of rubber tubing connected with the flask which is interposed between the water pump and the flask receiving the filtrate. A support for the tube and a metric rule completes the apparatus. The latter should touch the surface of the mercury. It is a good rule to do the filtration at as low a pressure as possible. Most

filtrates can be put through with sufficient rapidity at from 100 to 150 mm. of mercury. When the Berkefeld N filter candles are used, the pressure should never exceed 450 mm. of mercury, and bacteria will sometimes come through at that pressure.

The amount of water going through the vacuum pump should be just sufficient to maintain the pressure at the desired level. A pinchcock on the tubing, Fig. 1 (B), connecting the pump with the filtering flask aids in controlling the pressure and is particularly useful in eliminating the effect of sharp, quick changes in pressure in the water pipes. The orifice left open should be the smallest which will not cause the mercury to drop.

A very annoying thing, which sometimes occurs, is to have the pressure suddenly released when the pump is turned off and to see the cotton plug in the side arm forced into the flask. Refiltration is, of course, necessary since the filtrate is no longer sterile. Such accidents can be avoided by having a valve which will gradually release the pressure. A very simple type of valve is illustrated in Fig. 1 (B) and details are shown in Fig. 1 (C). It consists of a piece of glass tubing which extends through a rubber cork of an intervening flask placed between the water pump and the flask which receives the filtrate. The end of the tube is drawn out and rounded off in a flame until the opening is only about a millimeter in diameter. Over this is pushed a soft rubber stopper in which a hole has been pierced about two-thirds of the distance from the bottom to the top. The tightness of the rubber stopper around the outside of the glass tube prevents the entrance of the air until it is pulled off at the end of the filtration simultaneously with turning off the pump. Air gradually goes in through the small orifice, and the cotton plug in the side arm is not disturbed.

When small quantities are to be filtered, time can be saved and loss due to liquid remaining at the bottom of the mantle can be avoided by inverting a test tube over the filter candle. The tube should be of as small a diameter as possible to still go down to the bottom of the mantle. It should be placed over the candle before the liquid is poured into the mantle. If placed on after the candle is wet, the air is often never entirely exhausted from the inside of the tube, and the fluid level never rises.

Occasionally an accident occurs when taking the rubber stopper from the flask in order to remove the filtrate, particularly if a few drops of fluid happen to fall outside the mantle and down on the stopper. This difficulty can be overcome by removing the filtrate through the side arm, provided care has been taken that no fluid has run down the rubber tube into the side arm and has dampened the cotton. The cotton is removed from the side arm and the end carefully flamed. It is then held over the end of the tube or flask which is to receive the filtrate, as shown in Fig. 1 (D). A flame is applied to the bottom of the flask so that the heating of the air inside causes it to expand and forces the filtrate out. Without the heat the filtrate will not run out of the side arm. When flame is being applied to the side arm, care should be observed not to overheat it, as the liquid will then cause it to crack.

Washing the candles is simple when the arrangement shown in Fig. 1 (*E*) is used. The washing liquid placed in the beaker is pulled through the candle in the reversed direction. The only equipment necessary is a stopper through which a piece of glass tubing passes. The stopper fits snugly into the end of the mantel and the glass tubing is connected with the water pump.

More than one filter can be washed at the same time with the same pump when the arrangement illustrated in Fig. 1 (*B*) is used. Each rubber tube can be connected with a filter, either when filtering or when washing the filters. When only one tube is being used, the other tubes must be closed by a pinch-cock or by thrusting a piece of glass tubing closed at one end, illustrated in Fig. 1 (*F*), into the end of each rubber tube.

Splashing in the sink by the outflow of the water pump can be avoided by the use of a piece of rubber tubing which reaches to one-quarter of an inch of the bottom of the sink. Splitting the lower three or four inches of the tube also reduces the splashing (Fig. 1 *G*).

#### SUMMARY

The various aspects of the mechanics of bacterial filtration are discussed, methods of eliminating the frequent difficulties, which make refiltration necessary, being particularly considered.

Four useful additions to the usual technic are described:

1. A method of using or washing three or more filters simultaneously with the same pump.
2. An easily constructed vacuum release.
3. A simple method of removing the filtrate from the flask.
4. A means of avoiding splashing by the outflow of the water pump.

# DEPARTMENT OF REVIEWS AND ABSTRACTS

ROBERT A. KILDEFFE, M.D., ABSTRACT EDITOR

## B. TUBERCULOSIS, Viability and Virulence of Old Cultures of, Corper, H. J., and Cohn, M. L. *Am. Rev. Tuberc.* 28: 856, 1933.

In 1919 and 1920, several hundred 8 ounce nursing bottles containing about 3 ounces of 5 per cent glycerol-broth, neutral to litmus, were planted with 19 different strains of human and bovine tubercle bacilli, and were maintained at 37° C. from then until 1932, when 47 bottles containing cultures of human tubercle bacilli were chosen to determine the viability of the bacilli. Twenty (42.5 per cent) of these were found capable of growing on an inspissated egg yolk medium, while, from 9 bottles planted with bovine tubercle bacilli in 1920, four cultures (44.4 per cent) were viable in 1932 and grew on subculture.

Twelve strains of the original 1919 and 1920 cultures of 17 different strains of human tubercle bacilli subcultured in 1932 grew on the egg medium and were recovered for study and perpetuated, while, of two bovine strains, one grew and was recovered and was perpetuated.

There was noted a certain parallelism between the successful recovery of the bacilli in viable form and the  $P_H$  of the medium at the time of the attempt to grow the bacilli twelve years after planting. None of the transplants grew from bottles in which the acidity of the medium was below  $P_H$  6.1 or the alkalinity above  $P_H$  7.6.

A determination of the approximate number of live bacilli present in the culture masses revealed that about 0.01 per cent of the bacilli in the twelve-year-old culture mass of human tubercle bacilli were still viable, while about 1.0 per cent of the bovine bacilli were still able to grow, conforming to earlier observations by us and other investigators who found bovine tubercle bacilli more resistant to detrimental influences in general than human tubercle bacilli.

It was noted that all of the virulent strains of the twelve-year-old cultures of human tubercle bacilli had not suffered a diminution of virulence during twelve years' residence in the incubator at 37° C., while low-virulent strains remained of low virulence during this time. In contrast, prolonged and repeated artificial cultivation, however, caused a slight but definite diminution of virulence (a slow transition) of human tubercle bacilli in stock cultures. It would appear from this that virulence is a property inherent and unchangeable to individual bacilli but prolonged cultivation on artificial media may cause a perceptible, though not striking, change in the progeny of human tubercle bacilli under the ordinary conditions of laboratory perpetuation on culture media.

These observations also suggest a means for maintaining the original culture of a strain of bacilli as control for tests of methods to enhance or diminish virulence as well as to study other factors of the growth of tubercle bacilli.

The morphologic changes noted in the bacilli in the twelve-year-old cultures conformed to those previously described under the changes of the cytomorphosis of tubercle bacilli (1926).

In correlating these culture findings with *in vivo* conditions of the survival of tubercle bacilli it is evident that the persistence of the bacilli in the body is dependent upon a number of factors, but prominent among these, aside from the pathogenicity of the bacilli, is the factor of the number of tubercle bacilli introduced into the organs and tissues of an animal. This is evident from the fact that while small numbers of virulent tubercle bacilli in fine suspension are removed from the organs and tissues of the rabbit and dog within about one year, large amounts of even avirulent human tubercle bacilli can persist in the tissues of the dog in viable form for over three and a quarter years without the presence of characteristic histologic evidences of tuberculosis in these tissues.

**BLOOD, During the First Year of Life, Merritt, K. K., and Davidson, L. T.** *Am. J. Dis. Child.* 46: 990, 1933.

A group of normal American infants have been studied with reference to the behavior of their erythrocytes, hemoglobin, reticulocytes, and platelets throughout the first year, also the bleeding and coagulation time on the day of birth.

It is apparent that after a period of initial erythrocyte adjustment of two months' duration a mean value of 4.69 million, with a standard deviation of 0.37 million, may be considered as "normal" throughout the first year. After a similar initial period of adjustment, lasting two months, the mean value for hemoglobin for the first year is 12.6 gm. per hundred cubic centimeters, with a standard deviation of 1.36 gm. From these figures, it would appear that normal infants in New York City do not become anemic, as Mackay stated was the case in 51 per cent of artificially fed infants in London. It would seem that her "standard normal hemoglobin curve" is below what may be considered as "normal" in this country. In using Haden's scale of 15.6 gm. per hundred cubic centimeters, which is equivalent to 100 per cent, the color index is found to be 0.86. With Sahli's scale, 17 gm. per hundred cubic centimeters is equivalent to 100 per cent and the color index is therefore 0.90.

The reticulocytes in the normal infant are found to have a mean value of 3.1 per cent at birth. After a rapid drop through the first month, they reach a mean value of 0.16 per cent, with a standard deviation of 0.12 per cent, which is considered normal throughout the first year.

Blood platelets at birth are found to have a mean value of 227 ( $\pm 3.0$ ) thousand. After a rise at the third month, their mean value throughout the remainder of the first year is 344 thousand, with a standard deviation of 66 thousand. The figures at birth are lower than those of other investigators, and rise less rapidly.

Values for the bleeding time at birth are found to be from one-half to two and one-half minutes. The coagulation time at birth is from two to four minutes.

NOTE: Since this article was accepted for publication, Mackey has published an article, "The Normal Hemoglobin Level During the First Year of Life—Revised Figures," in which it was stated that owing to necessary restandardization of her hemoglobin apparatus, it is necessary to add 7 per cent to each value quoted in her monograph (1931).

**LIVER FUNCTION, In Catarrhal Jaundice, Jolliffe, N.** *Am. J. M. Sc.* 186: 640, 1933.

In 19 cases of the type customarily regarded as catarrhal jaundice it has been found that a definite pathologic and physiologic syndrome was present in 16 of the 19. This consists of a regurgitational jaundice which runs through three distinct stages:

a. An "obstructive phase" with an average duration of eleven days in which there is a progressive deepening of the icterus, absent or mere traces of urobilin in the urine, a retention of bromsulphalein paralleling the degree of jaundice and, usually (87.5 per cent), a positive levulose tolerance test.

b. A "critical phase" with an average duration of four days in which urobilin suddenly appears in the urine in high normal or definitely elevated amounts, a coincident abrupt fall in serum bilirubin and bromsulphalein retention.

c. A "recovery phase" with an average duration of nine days during which time the serum bilirubin falls within the level of latent icterus, urobilin is present in the urine in normal amounts and the tolerance to levulose and the retention of bromsulphalein return to normal.

The term "catarrhal jaundice" should be limited to subjects showing this pathologic and physiologic syndrome.

The 3 remaining cases were of distinctly different pathologic and physiologic types. It is suggested that these types may be appropriately designated as acute hepatitis of unknown etiology with, as the case may be, retentional or regurgitational jaundice.

**BLOOD SUGAR, In Schizophrenia, Freeman, W. Am. J. M. Sc. 186: 621, 1933.**

A study is presented of the fasting blood sugar levels as disclosed by 6 samples taken at standard intervals from 59 male schizophrenic patients over a period of six and one-half months.

In 95 per cent of 347 determinations the values lay between the conventional limits of normality, namely, 80 and 120 mg. per 100 c.c. The average value was 96.6 as compared with an average of 95.4 in 31 normal control subjects studied by the same technic. Eight readings were obtained in the hypoglycemic and 8 in the hyperglycemic ranges.

The variation among the schizophrenics was higher than that in the controls, as was shown by the coefficients of variation, 11 and 6.9 per cent, respectively.

The samples were collected in pairs at fifteen-day intervals with intervening periods of two and one-half months. There was a consistent drop in the average blood sugar level from period to period, the first being 99.3 and the third 93.1 mg. per 100 c.c. These findings suggest that habituation with a presumable lessening of emotional reaction to the test played a part in determining the sugar level.

The range of difference in consecutive tests also decreased consistently from one period to another; in the first the average difference was 10.6 and in the last 8 mg. per 100 c.c.

No significant correlation could be recognized between the blood sugar level and the age, period of hospitalization, or severity of the psychosis.

Of the subgroups, the hebephrenics showed the highest average level, namely, 99.7 mg., and the catatonics the lowest, namely 92.7 mg.

**DYSENTERY, Amebic, Unusual Experience With. Ikeda, K. J. A. M. A. 101: 1944, 1933.**

Nine cases of amebic dysentery were recognized within a period of forty-seven days in a general hospital of an average size, in a northern city of 250,000 population, in the United States. This is a unique experience. Infection in all nine cases was definitely traced to Chicago, which demonstrates, probably, a widespread dissemination of this disease throughout the country as a direct result of the Chicago epidemic.

The presenting symptoms show a wide variation, depending on the character of the attack and on the stage of the disease.

The initial symptoms, when elicited, are not always identical. There are atypical cases in which the first symptoms may be misleading or so insignificant and commonplace that no medical relief is considered necessary by the patient.

There is danger of a false positive report in the laboratory diagnosis of this disease by the inexperienced. Careful and painstaking search for the organism should be undertaken in suspected and neglected cases.

Röntgen examination may be of value as an aid in differential diagnosis.

Amebas were demonstrated in a section of a piece of tissue from the rectum, in a case suggesting a malignant growth. The histologic appearance of the lesion presents the characteristic initial changes due to the invasion of *Endamoeba histolytica*.

**TUBERCULOSIS, A Hematological Retrospect, Oatway, W. H., Jr. Am. Rev. Tuberc. 29: 73, 1934.**

The author recapitulates the types of blood picture seen in tuberculosis described by him in 1929 as follows:

1. *Normal*.—The total count and each of the cell-types are within certain normal limits. (Total cells, 6,000 to 9,000; neutrophils, less than 65 per cent, or 5,000 cells; monocytes, less than 10 per cent, or 700 cells; lymphocytes, more than 25 per cent, or 2,000 cells.) It denotes a lack of pathological activity in the lesion, a controlled condition.

2. *Hyperplastic*.—An increase in the mononuclear leucocytes above normal number (more than 9 per cent, or 700 cells). The total count, lymphocytes, and neutrophils are of normal numbers. It denotes new tubercle-formation. A fairly passive type of reaction, both clinically and pathologically.

3. *Septic*.—Primarily an increase of the neutrophiles (more than 65 per cent, or 5,000 cells). There is often an increase of the total count (more than 9,000 cells), and monocytes (more than 9 per cent, or 700 cells), with a lymphopenia (less than 25 per cent, or 2,000 cells). It denotes tuberculous abscess-formation in some degree and is the most serious type of count, associated with all of the more active features of the disease. The level of septicity is, in general, an indicator of the magnitude of the disease process.

A lymphocytosis (more than 32 per cent) added to a normal or hyperplastic count was seen in more favorable conditions (resistant). Single counts were of most value in showing the tuberculous condition only at the time of the count. Repeated counts were recommended to show the trend of the disease. Very few counts were "out of focus" with the actual condition of the patients. A deviation occasionally found was a slightly septic picture in a patient apparently handling the lesion well. Two patients had large lesions and only a hyperplastic blood picture. Such cases were left in the balance for a later judgment.

Previous conclusions as to the meaning and the relative seriousness of the types of leucocyte pictures have been somewhat further reaffirmed by this study of the fate of 250 cases after over three years.

The septic count is the most dangerous type of the blood picture, and is present most often when death occurs, when the illness becomes chronic, or when there is need of surgery. The hyperplastic count is less favorable than the normal and less serious than the septic count. Monoctosis adds to the danger of the septic count when present. The normal count is very good to attain, and a lymphocytosis makes it of even better import.

Compression therapy, especially pneumothorax, has often interrupted the prognosis of an unfavorable count, and in spite of its risks and failures has no doubt modified from poor to good the conditions and counts of many patients. Its use most frequently in cases with septic counts has often modified the course of the disease and the prognosis of the blood picture in this group.

There is nothing in this further survey to suggest that the previous limits or interpretation should be changed or ignored. Although the interpretation of the blood count in a tuberculous individual should be limited to his immediate condition, the fate of 250 patients has been consistent, in general, with the portent of three years or more ago. In spite of this prescient value of one blood count, following the condition of the disease by sedulously repeated counts, care in the interpretation, and a constant adherence to the meaning is the recommended use of the procedure, and it will provide a valuable clinical adjunct in diagnosis of the patient's condition and in surgery.

**ALLERGY: Recent Immunologic Studies in Hypersensitivity to Tobacco, Sulzberger, M. B.**  
*J. A. M. A.* 102: 11, 1934.

The studies reported were carried out, in the main, by means of intradermal tests of the skin with tobacco extracts and with nicotine in cases of thromboangiitis obliterans.

Six concepts of fundamental immunologic nature form the basis of the hypothesis that some cases of certain diseases of the vascular system (thromboangiitis obliterans, angina pectoris and coronary disease), clinically long considered to be in some way connected with smoking, are manifestations of hypersensitivity in certain segments of blood vessels to circulating allergens derived from or contained in tobacco.

Concept 1: There is localized and circumscribed fixed specific hypersensitivity; i.e., a hyper-sensitivity confined to a certain organ or part of an organ may develop.

Concept 2: There is a predilection of certain allergens to sensitize and elicit reactions in certain tissues; i.e., whereas any allergen may sensitize any part, almost all allergens have their favorite point of attack.

Concept 3: Not only sudden and evanescent reactions are elicited when the excitant meets the specifically sensitized shock tissue, but chronic reactions and permanent organic damage are often caused by one or successive shocks resulting from such encounters.

Concept 4: There is an idiosyncrasy, meaning that certain persons react in a manner different from that of the norm; allergens causing reactions in the idiosyncratic person cause

no reactions in normal persons. Allergens are thus usually of harmless nature and are not poisons or toxins in the pharmacologic or toxicologic sense.

Concept 5: The vascular system in man seems to be peculiarly susceptible to sensitizations and is thus most frequently the seat of reactions. Examples of this are found in many diseases of the skin. The wheal reaction is, in itself, a demonstration of vascular hypersensitivity.

Concept 6: The skin is useful as a test tissue in a great variety of hypersensitivities of internal organs.

The experiments in patients with thromboangiitis obliterans and in controls have brought to light the following data: 78 per cent of the patients with thromboangiitis obliterans tested had positive reactions of the skin to tobacco; 36 per cent of the smokers without thromboangiitis obliterans; and 16 per cent of the nonsmokers gave positive reactions.

The persons afflicted with thromboangiitis obliterans were not atopic, and there were no regularly demonstrable reagins in their serums.

As the positive skin tests in patients with thromboangiitis obliterans correspond with the clinical evidence incriminating tobacco, these results are regarded as highly suggestive that sensitization of the vascular system to tobacco may play a causal or contributory rôle in many cases of thromboangiitis obliterans.

Although tobacco was the principal allergen causing positive reactions of the skin in thromboangiitis obliterans, other allergens and, notably, inhalants also elicited positive responses.

It is assumed that cases of thromboangiitis obliterans must exist in which other excitants and not tobacco are the major factors.

That part of the tobacco which elicits the skin reaction of hypersensitivity is coctostable and thermostable and is not destroyed by ultraviolet rays or x-rays in the dosages employed. It is not nicotine.

Nicotine is of little or no importance in sensitizations to tobacco. If the diseases under discussion are sensitizations to tobacco, nicotine is, in all probability, of little or no importance in their causation.

It is hoped that the new immunologic approach and the employment of animal sensitizations will lead to the experimental reproduction of certain diseases clinically attributable to damage by tobacco. As is well known all toxicologic attempts to do this have failed.

One of the objects of such experimental studies would be to isolate and, eventually, to eliminate the actual sensitizing factor or factors from tobacco.

**LIVER FUNCTION, In Advanced Pulmonary Tuberculosis, Steidl, J., and Heise, F. H.**  
*Am. J. M. Sc.* 186: 631, 1933.

In a series of 23 patients having advanced pulmonary tuberculosis all but one gave pathologic readings in one or more of a group of 5 tests for hepatic function. Of the tests used, the cinchophen test, the icterus index and the galactose test were the most sensitive in the order named.

### The Epidemiology of Amebic Infection

WE HAVE good reason to hope that the great interest in amebiasis, stimulated by the recent Chicago epidemic will be productive of a greatly increased knowledge concerning the epidemiology of this condition. The general understanding based upon reports in the current medical literature is that the Chicago epidemic was the result of food infection following contamination of the food by food handlers, either healthy carriers or individuals mildly ill with amebic colitis. The official report later incriminated defective plumbing systems in the old hotels, in which there was some sort of cross connection between the sewage system and the water supply, such that, with overload, the water supply could become contaminated.

There can be no doubt in view of the reports by Bundesen, of the extremely high incidence of carriers of *Endameba histolytica*, in the hotels chiefly responsible for the epidemic that food contamination played a part, possibly also infected water supply.

The review of the measures for the control of amebic dysentery recently enumerated by McCoy are of great interest in connection with the epidemic. After emphasizing that we do not have sufficient information concerning the factors governing transmission, on which to base authoritative measures, and that the present facts do not justify some of the various measures being put into effect, McCoy summarized present epidemiologic information as follows:

There is very little evidence that the cases originating in Chicago have led to any considerable spread of the infection in other communities into which the infective individuals have gone.

Carriers do not appear as much of a menace as they had been thought to be. There is no clear evidence that carriers, even among food handlers, are important in transmission.

Large scale control of spread by detection of carriers and their removal from food-handling groups appears not practicable.

There is no need for isolation of clinical cases beyond that necessary for the benefit of the patient. There is no need for isolation of carriers.

In the absence of modern methods of sanitary sewage disposal precautions should be taken to prevent water supply contamination and fly contamination. Otherwise no precautions need be taken.

Persons exposed to clinical cases or carriers need no particular attention.

Measures which should be taken by health officers consist in calling the attention of practicing physicians to the importance of recognizing dysentery; insistence upon reporting all cases of dysentery; distinguishing between the amebic and bacillary forms; the provision of facilities for diagnosis; educational measures among food handlers with regard to cleanliness; feces examination of food handlers, measures to prevent possible contamination of drinking water supply, especially in hotels and public eating places.

Spector and Buky report a laboratory investigation in which feces containing ameba histolytica was allowed to dry upon the hand, to determine the viability of cysts. They conclude that the majority of cysts under the circumstances of the experiment were dead at the end of five minutes and that it was very exceptional for any to survive beyond ten minutes.

We infer that the public health service in the discussion just reviewed, are not taking the attitude of the town crier, "twelve o'clock and all's well." Instead, McCoy has presented an analysis of the actual facts as we know them today, with what conclusions are justified by those facts. The reader who does not realize this might be lulled into a false sense of security. The Chicago epidemic was very real, has already caused a very respectable number of deaths, and, as the years go on, will probably be responsible for a great deal of individual illness, the cause of which may remain undetermined. The disease is of sufficient importance, that all promising measures should be taken to prevent its spread, even though some of them may not be completely justified by the facts. Of course one recalls that entire Cuban villages were put to the flame, to destroy yellow fever, which nevertheless returned the next year on schedule. But such useless destruction is not a phase of the prevention of amebic infection.

The clinician is possibly in a better position to study the family incidence of amebiasis than the public health man, and it is this phase of the epidemiology that we would prefer to stress. The reports in the literature together with the experience of all clinicians who see any amount of amebic infection, offer convincing evidence of contact transmission in the family. It seems to us that for the present at least every possible precaution should be taken to recognize amebic infection among food handlers, both in public eating places and in the home, and to prevent this source of food contamination.

Craig, Kofoed and others have for years been preaching the wide distribution of this malady. To an extent they have been crying in the wilderness, but the Chicago epidemic has fully justified their contentions.

Craig emphasizes that, although infection with *ameba histolytica* is more prevalent in the South than in the North, scarcely a state in the country is free from it, and a conservative estimate indicates that between 5 and 10 per cent of the population of the country, as a whole, harbor the parasite. The majority of infected individuals in this country do not develop frank amebic dysentery, as they do in the tropics.

He states that the cysts are the infecting agents. Under normal conditions the motile trophozoites are destroyed by the gastric juice. Persons suffering with acute amebic dysentery do not have cysts in the stools. They are, therefore, of little importance in contagion. It is the individual with few symptoms and the healthy carrier, who has cysts, who are according to Craig the more important epidemiologic consideration. Acute cases untreated or improperly treated, become carriers of cysts.

He finds that transmission through contaminated water supply is common in localities without modern supply and plumbing systems, particularly when wells, springs, and tanks are depended upon for water. The cysts may live for days and even weeks in water, depending upon the temperature and the number of bacteria present. This method of transmission is of importance in this country only in rural districts. "Wherever sanitation and personal hygiene is poor, amebiasis is very prevalent, whether in the tropics, subtropics, or the temperate zones."

Human excreta used for fertilizer is more of a factor in the Orient than in this country. The cysts will remain viable in moist feces for as long as two weeks. Craig also believes that fly contamination is a distinct factor.

"The transmission of the infection by food handlers is practically a certainty unless the greatest care is taken regarding personal hygiene and the cleanliness of the hands of all who handle food. The incidence of infection in food handlers employed in public eating places is often very high, due to their close association and the constant intake of the cysts in food which they themselves contaminate, and one infected food handler may infect many others with whom he is associated, until the vast majority of the food handlers in a particular institution may show infection."

Craig also emphasizes that there has been no convincing evidence of variation in virulence with different strains of *Endameba histolytica*. Walker and

Sellards successfully produced acute amebic dysentery in human volunteers, with cysts obtained from symptomless carriers.

During the next few years it is obligatory upon all clinicians and clinical laboratory workers to emphasize and reemphasize the importance of careful study of every patient with indefinite or unidentified gastrointestinal symptoms, particularly colonic symptoms, with the possibility of chronic low grade amebic infection in mind. Fortunately, two reliable methods are available, direct examination for motile ameba and for cysts, and the complement fixation reaction which has been developed by Craig.

## *CLINICAL AND EXPERIMENTAL*

### THE ETIOLOGY OF GRANULOPENIA (AGRANULOCYTOSIS)\*

WITH PARTICULAR REFERENCE TO THE DRUGS CONTAINING THE  
BENZENE RING

ROY R. KRACKE, B.S., M.D., AND FRANCIS P. PARKER, B.S., M.D.  
EMORY UNIVERSITY, GA.

THE disease known as agranulocytosis was described as a clinical entity only eleven years ago.<sup>1</sup> The first case in the United States was reported nine years ago.<sup>2</sup> Since that time it has been constantly on the increase and at this time we have collected 473 cases from the American and Canadian literature alone. It is apparently increasing in frequency and also being recognized more readily.

In our review of the American cases we have been impressed by the consistently increasing number of the acute fulminant types and also by the large number of so-called chronic granulopenic patients as reported by Roberts and Kracke.<sup>3</sup>

It is quite probable that the so-called acute granulopenia in which the granulocytes entirely disappear from the peripheral blood represents only a fraction of the total number of individuals whose blood count is depressed to some degree. Although there was a sporadic case of this disease prior to 1922, it certainly must have occurred very infrequently.

Pepper<sup>4</sup> believes that it was quite common many years ago and cites the numerous instances of so-called putrid sore throat or malignant angina. But

\*From the Department of Pathology, Emory University School of Medicine.

Received for publication, November 15, 1933.

Read in Section on Pathology, Southern Medical Association, Twenty-Seventh Annual Meeting, Richmond, Virginia, November 14 to 17, 1933.

this assumption is entirely unwarranted since the single diagnostic criterion, namely, a low leucocyte count, was lacking in these cases. The disease is one that is easily diagnosed, runs a dramatic and clear-cut clinical course, and the fact that it was not observed before 1922 is practical assurance that it did not exist before that time. To state otherwise would be to reflect on the diagnostic acumen of our clinicians of the past. Blood counts have been taken for fifty years. We must consider, then, that granulopenia is a disease of modern times and one that has come among us during the past ten years.

#### ETIOLOGY

*Live Bacteria.*—Since the first report of Schultz<sup>1</sup> in Germany and the report of Lovett<sup>2</sup> in the United States, many investigators have directed their efforts toward the solution of the etiologic factors. Up to this time these efforts have met with very little or no success. It is the chief purpose of this paper to present briefly a summation of the work in this field and to formulate an hypothesis for the cause of granulopenia and to present evidence supporting this view.

Lovett<sup>2</sup> noted in her case the presence of mouth ulcers infected with *B. pyocyaneus* and at once suspected this organism as etiologic. She injected numerous laboratory animals but failed to produce the condition.

Similar observations have been made by Linthicum,<sup>3</sup> Windham,<sup>4</sup> Keeney,<sup>5</sup> Also, Friedmann<sup>6</sup> in a study of 23 cases found *B. pyocyaneus* in the blood stream of one. It will be noted that this same organism has been found in the blood stream of three of the American cases (Table I). These findings have led many to suspect it as etiologic but up to this time efforts to reproduce the disease in laboratory animals with it, have been unsuccessful. There is little support for the bacterial etiology of granulopenia since it has been well demonstrated by Roberts and Kracke<sup>7</sup> that the basic pathology is first, the disappearance of the neutrophils, and this in turn is followed by the invasion by any and every organism that is accessible, particularly throughout the entire length of the gastrointestinal tract. Most writers are in accord with the conception that granulopenia is first a disease of the bone marrow, followed by disappearance of peripheral granulocytes, this in turn followed by varying degrees and types of infectious processes.

It will be noted from a study of Table I that at least 25 organisms have been found as blood stream invaders in this disease and that approximately 20 per cent of the cases show blood stream infection. The wide variety of invading bacteria can also be noted from the numerous types that are responsible for the ulcers. A few reports tending to incriminate various organisms have been made. Notable among these is the work of Fried and Dameshek<sup>8a</sup> in which they reported the production of primary granulopenia in rabbits by the intravenous injection of *Salmonella Suipestifer*. An analysis of their report shows that in no instance did they reproduce the condition as it is observed clinically, since they failed to produce a sustained and prolonged depression of the leucocyte count, but did produce a temporary neutropenia which, as has been well demonstrated, will follow the injection of any killed organisms or other matter in a finely divided state.

TABLE I  
 BLOOD STREAM INFECTION IN GRANULOPENIA

| ORGANISM                                 | NUMBER OF CASES |
|------------------------------------------|-----------------|
| <i>Streptococcus hemolyticus</i>         | 8               |
| <i>Streptococcus viridans</i>            | 15              |
| <i>Streptococcus</i> (type undetermined) | 9               |
| <i>Staphylococcus albus</i>              | 3               |
| <i>Staphylococcus aureus</i>             | 4               |
| <i>Bacillus Friedlander</i>              | 4               |
| <i>Pneumococcus</i> , Type 2             | 3               |
| <i>Pneumococcus</i> , Type 3             | 1               |
| <i>Pneumococcus</i> , Type 4             | 2               |
| <i>Pneumococcus</i> , Type undetermined  | 2               |
| <i>Diplococcus</i> (undetermined)        | 4               |
| <i>Bacillus pyocyaneus</i>               | 3               |
| <i>Bacillus paratyphosus</i> B.          | 1               |
| <i>Bacillus coli</i>                     | 3               |
| <i>Bacillus proteus</i>                  | 1               |
| <i>Streptothrix</i>                      | 3               |
| <i>Streptococcus</i> with other bacteria | 9               |
| <i>Fusiform bacillus</i> (Gram negative) | 1               |
| Estivo-autumnal parasites                | 1               |
| <i>Varines cocci</i>                     | 3               |
| <i>Staphylococcus</i> (undetermined)     | 1               |
| <i>Diphtheria bacillus</i>               | 1               |
| Vincent's organisms                      | 1               |
| Typhoid bacillus                         | 1               |
| <i>Bacillus</i> (undetermined)           | 1               |
| Total number of positive cultures        | 74              |
| Negative, or not stated                  | 395             |

1. Blood cultures are positive in about 20 per cent of the total number of cases or positive in 70 per cent of the examined cases.

2. The streptococci are the most frequent invaders.

3. The blood stream infection is probably secondary to the leucopenic state.

The clinical onset of many cases of granulopenia has been preceded by tooth extractions, treatment for pyorrhea, mouth ulcers, etc. It will be noted in a study of Table II that this is a common history and in many of these cases Vincent's organisms have been isolated. We believe that these oral

 TABLE II  
 IMPORTANT FEATURES OF THE HISTORIES

|                                                      |    |
|------------------------------------------------------|----|
| Tooth extraction                                     | 27 |
| Treatment for pyorrhea, etc.                         | 22 |
| Treatment for syphilis                               | 22 |
| Influenza (mild)                                     | 17 |

| Sudden onset (no premonitory symptoms)               | 91 |
| Various operations                                   | 48 |
| Abscesses and furunculosis                           | 8  |
| Arthritis                                            | 7  |
| 93 other clinical conditions, 1 to 2 in each patient | 6  |
| Not stated adequately                                | 77 |

1. Whether or not the numerous instances of dental therapy preceding the disease are the results of a previously unrecognized leucopenia has not been settled.

2. Nearly three-fourths of all reported cases had been receiving treatment for some other disease for variable periods prior to their attacks of granulopenia.

3. It is interesting that eight patients developed the disease while in a hospital for treatment for other conditions.

this assumption is entirely unwarranted since the single diagnostic criterion, namely, a low leucocyte count, was lacking in these cases. The disease is one that is easily diagnosed, runs a dramatic and clear-cut clinical course, and the fact that it was not observed before 1922 is practical assurance that it did not exist before that time. To state otherwise would be to reflect on the diagnostic acumen of our clinicians of the past. Blood counts have been taken for fifty years. We must consider, then, that granulopenia is a disease of modern times and one that has come among us during the past ten years.

#### ETIOLOGY

*Live Bacteria.*—Since the first report of Schultz<sup>1</sup> in Germany and the report of Lovett<sup>2</sup> in the United States, many investigators have directed their efforts toward the solution of the etiologic factors. Up to this time these efforts have met with very little or no success. It is the chief purpose of this paper to present briefly a summation of the work in this field and to formulate an hypothesis for the cause of granulopenia and to present evidence supporting this view.

Lovett<sup>2</sup> noted in her case the presence of mouth ulcers infected with *B. pyocyaneus* and at once suspected this organism as etiologic. She injected numerous laboratory animals but failed to produce the condition.

Similar observations have been made by Linthicum,<sup>3</sup> Windham,<sup>4</sup> Keeney.<sup>7</sup> Also, Friedmann<sup>8</sup> in a study of 23 cases found *B. pyocyaneus* in the blood stream of one. It will be noted that this same organism has been found in the blood stream of three of the American cases (Table I). These findings have led many to suspect it as etiologic but up to this time efforts to reproduce the disease in laboratory animals with it, have been unsuccessful. There is little support for the bacterial etiology of granulopenia since it has been well demonstrated by Roberts and Kracke<sup>9</sup> that the basic pathology is first, the disappearance of the neutrophils, and this in turn is followed by the invasion by any and every organism that is accessible, particularly throughout the entire length of the gastrointestinal tract. Most writers are in accord with the conception that granulopenia is first a disease of the bone marrow, followed by disappearance of peripheral granulocytes, this in turn followed by varying degrees and types of infectious processes.

It will be noted from a study of Table I that at least 25 organisms have been found as blood stream invaders in this disease and that approximately 20 per cent of the cases show blood stream infection. The wide variety of invading bacteria can also be noted from the numerous types that are responsible for the ulcers. A few reports tending to incriminate various organisms have been made. Notable among these is the work of Fried and Dameshek<sup>10</sup> in which they reported the production of primary granulopenia in rabbits by the intravenous injection of *Salmonella Suipestifer*. An analysis of their report shows that in no instance did they reproduce the condition as it is observed clinically, since they failed to produce a sustained and prolonged depression of the leucocyte count, but did produce a temporary neutropenia which, as has been well demonstrated, will follow the injection of any killed organisms or other matter in a finely divided state.

TABLE I  
BLOOD STREAM INFECTION IN GRANULOPENIA

| ORGANISM                                 | NUMBER OF CASES |
|------------------------------------------|-----------------|
| <i>Streptococcus hemolyticus</i>         | 8               |
| <i>Streptococcus viridans</i>            | 15              |
| <i>Streptococcus</i> (type undetermined) | 9               |
| <i>Staphylococcus albus</i>              | 3               |
| <i>Staphylococcus aureus</i>             | 4               |
| <i>Bacillus Friedlander</i>              | 4               |
| <i>Pneumococcus</i> , Type 2             | 3               |
| <i>Pneumococcus</i> , Type 3             | 1               |
| <i>Pneumococcus</i> , Type 4             | 2               |
| <i>Pneumococcus</i> , Type undetermined  | 2               |
| <i>Diplococcus</i> (undetermined)        | 4               |
| <i>Bacillus pyocyaneus</i>               | 3               |
| <i>Bacillus paratyphosus</i> B.          | 1               |
| <i>Bacillus coli</i>                     | 3               |
| <i>Bacillus proteus</i>                  | 1               |
| <i>Streptothrix</i>                      | 3               |
| <i>Streptococcus</i> with other bacteria | 9               |
| Fusiform bacillus (Gram negative)        | 1               |
| Estivo-autumnal parasites                | 1               |
| Varines cocci                            | 3               |
| <i>Staphylococcus</i> (undetermined)     | 1               |
| Diphtheria bacillus                      | 1               |
| Vincent's organisms                      | 1               |
| Typhoid bacillus                         | 1               |
| <i>Bacillus</i> (undetermined)           | 1               |
| Total number of positive cultures        | 74              |
| Negative, or not stated                  | 395             |

1. Blood cultures are positive in about 20 per cent of the total number of cases or positive in 70 per cent of the examined cases.

2. The streptococci are the most frequent invaders.

3. The blood stream infection is probably secondary to the leucopenic state.

The clinical onset of many cases of granulopenia has been preceded by tooth extractions, treatment for pyorrhea, mouth ulcers, etc. It will be noted in a study of Table II that this is a common history and in many of these cases Vincent's organisms have been isolated. We believe that these oral

TABLE II  
IMPORTANT FEATURES OF THE HISTORIES

|                                                      |    |
|------------------------------------------------------|----|
| Tooth extraction                                     | 27 |
| Treatment for pyorrhea, etc.                         | 22 |
| Treatment for syphilis                               | 22 |
| Influenza (mild)                                     | 17 |
| Tonsillectomy                                        | 5  |
| Sore throat                                          | 85 |

| Malaise and weakness                                 | 91 |
| Sudden onset (no premonitory symptoms)               | 48 |
| Various operations                                   | 8  |
| Abscesses and furunculosis                           | 7  |
| Arthritis                                            | 6  |
| 93 other clinical conditions, 1 to 2 in each patient |    |
| Not stated adequately                                | 77 |

1. Whether or not the numerous instances of dental therapy preceding the disease are the results of a previously unrecognized leucopenia has not been settled.

2. Nearly three-fourths of all reported cases had been receiving treatment for some other disease for variable periods prior to their attacks of granulopenia.

3. It is interesting that eight patients developed the disease while in a hospital for treatment for other conditions.

manifestations are secondary to a preceding neutropenic state. It must be borne in mind that when the granulopenic patient consults a physician he presents the terminal stage of a condition that has existed possibly for many months. And, furthermore, many people have developed acute fulminant granulopenia and have died without showing any ulcers whatever. There has been no experimental or clinical evidence to indicate that Vincent's organisms are capable of producing a severe and sustained leucopenic state.

There are many reports in the literature concerning the efforts of various investigators to reproduce the disease in laboratory animals with organisms that have been isolated from their respective patients, but all of this work has been unsuccessful. Piersol and Steinfeld<sup>10</sup> injected intravenously into rabbits inactivated cultures, Berkefeld filtrates, and supernatant fluids of cultures of many organisms and failed to reproduce the condition and called attention to the fact that a temporary leucopenia may be produced by the injection of peptones and a large number of other proteins.

It has been stated that granulopenia may be due to the continued absorption of toxins from sites of focal infection. The recent work of Dennis<sup>11</sup> is important. He was able to produce a sustained and marked leucopenia in rabbits in which he allowed the *Streptococcus viridans* to grow in the tissue under such conditions that the toxins were diffused throughout the animal body while the organisms remained in situ. His results were not conclusive in the use of *Staphylococcus aureus*, *Streptococcus hemolyticus*, and *B. proteus*. It will be noted from a study of Table I that *Streptococcus viridans* has been reported as the most frequent blood stream invader in this disease. Dennis<sup>12</sup> stated later that a weakness of his experimental work consisted in the use of a very large dose in relation to the size of the animal. It has long been known, of course, that overwhelming infection with certain organisms will produce variable degrees of leucopenia.

*Dead Bacteria.*—The injection with dead bacteria in the course of vaccination has been suggested as a possible cause. Bromberg and Murphy<sup>13</sup> reported a typical case following a series of typhoid vaccine injections. Kracke<sup>14</sup> has reported a similar case in which, however, the patient had taken so much phenacetine during the previous four-year period that she was suffering from a severe sulphhemoglobinemia. Dr. R. P. Irwin<sup>15</sup> of Moulton, Ala., has submitted a record of a typical case following typhoid vaccination. In his case, also, the patient was under treatment for various other conditions in which she was given considerable medication of various types. Pepper<sup>4</sup> has advanced the conception that the disease may be allergic in nature, but there is little evidence to support his view.

*Glandular Dysfunction.*—The influence of the endocrine glands on the output of both granulocytes and erythrocytes has been studied considerably and has long been suspected.

Hubble<sup>16</sup> summarizes this work and postulates that bone marrow depression may be caused by a pituitary basophilic insufficiency, and he states that there is much evidence to indicate that granulopenia may be caused by cortical adrenal dysfunction.

Britton and Corey<sup>17</sup> have reported that experimental adrenal insufficiency in cats resulted in a marked degree of neutropenia with the return of the granulocytes to normal following administration of corticoadrenal extract. They did not produce, however, the typical granulopenic syndrome as is commonly seen.

Jaffe<sup>15</sup> has studied a patient with generalized infiltration of lymphadenoma which included invasion and destruction of the adrenal cortex with the patient finally dying with a typical granulopenia. He infers from this that the granulopenia was due to a cortical adrenal insufficiency.

Kunde et al.<sup>19</sup> have noted the production of a hypoplastic and aplastic bone marrow in thyroidectomized rabbits. Evidence accumulated indicates that the ductless glands in their various relationships have an effect on the output of blood cellular elements. This conception, however, will have to await further confirmation.

*Radiation.*—Excessive exposure to radiation has been suspected as a possible etiologic factor. It is known that Thorium X will produce a marked neutropenia in animals and in the human being. It is conceivable, of course, that excessive roentgen radiation can produce marked bone marrow depressions, and it should be used with caution in the therapy of this disease. Also, it will be noted from a study of Table III that granulopenia is a disease essentially of the white race, being quite rare in negroes, and this may have some relationship to the radiation theory.

*Bone Marrow Idiosyncrasy.*—This rather ill-defined conception includes the opinions of a considerable number of writers all of whom postulate that an occasional individual has a weakened or faulty bone marrow which will become nonfunctional if submitted to undue strain or stimulation.

Beck,<sup>20</sup> in her excellent review of this disease, holds the view that the primary pathology will not be found in the marrow itself, but in that particular organ or tissue which regulates granulopoiesis. She believes that those cases showing peripheral neutropenia but with a normal bone marrow would

TABLE III  
THE INCIDENCE OF GRANULOPENIA

|                                      |     |
|--------------------------------------|-----|
| Number of cases in the United States | 473 |
| Number of cases in the white race    | 442 |
| Number of cases in the colored race  | 8   |
| Race not stated                      | 23  |
| Number of cases in males             | 161 |
| Number of cases in females           | 310 |
| Sex not stated                       | 2   |

1. The disease is essentially one of the white race.

2. It exists in the ratio of two females to one male.

be due to a lack of the chemotactic factor, whereas the damaged bone marrow would be due to a lack of the maturation factor. As Beck infers, it is true that the bone marrow in some cases, both at autopsy and sternal biopsy, shows a normal or hyperplastic state while other cases show a definite aplasia of the marrow.

Fitzhugh and Krumbhaar<sup>21</sup> are of the opinion that the bone marrow may be hyperplastic up to the myelocytic level but that maturation ceases at that point.

Kracke<sup>22</sup> has studied a case which showed a definite hyperplastic bone marrow at sternal puncture at a time when the peripheral cell count was 500. This was explained four days later when the count reached 25,000. Finally this patient died with a second attack, showing a markedly aplastic bone marrow at autopsy.

If Beck's conception is correct, it follows that there is sometimes a temporary restriction of either the maturation or the chemotactic factor. Her theory, however, does not explain why such derangement occurs.

*Chemicals.*—It has long been known that various chemicals will depress the marrow function, resulting in complete inhibition of all cellular types. For example, benzene poisoning has been recorded as a process in which hematopoiesis is completely inhibited in all of the three bone marrow elements, resulting in a picture simulating aplastic anemia. It has been shown by Kracke<sup>23</sup> that benzene may be introduced into the rabbit in such small doses that it exerts a selective affinity for the granulopoietic tissue only, leaving the erythrocytic and thrombocytic elements relatively undisturbed. This same situation is conceivably true with other bone marrow depressing agents, and, no doubt, is true in the case of arsphenamine. Arsphenamine poisoning is a known etiologic agent in the production of bone marrow depression. The clinical picture resulting has been chiefly one of anemia, associated with granulopenia and thrombocytopenia as well. It will be noted from a study of Table II that at least 22 of the cases of granulopenia have been preceded by arsphenamine therapy, and there is little doubt that the drug was etiologic in that particular group of cases. But still more important, it shows that arsphenamine is capable of producing a type of bone marrow depression restricted chiefly to granulopoiesis to such an extent that the clinical syndrome resulting cannot be differentiated from true idiopathic granulopenia.

It has been shown that the injection of the human being with certain preparations of gold will produce a condition closely simulating, if not identical, with true granulopenia. Many such cases have been reported from France, Achard et al.,<sup>24</sup> Ameuille and Braillon,<sup>25</sup> Angeras and Ginsbourg.<sup>26</sup>

The fact that typical granulopenia can be produced with gold preparations and with arsphenamine preparations which contain the benzene ring is evidence that this class of products can, and in some instances does, manifest a selective action on the granulopoietic tissue only. It seems, therefore, in the study of etiology that it becomes our problem to determine which of these chemicals has come into wider usage and closer contact with our people during the last ten-year period or during the period of agranulocytosis.

#### THE INCIDENCE OF GRANULOPENIA

Our review of the reported cases in the United States and Canada has uncovered many interesting findings in connection with the occurrence of this disease.

*Geographic Distribution.*—We have collected from the literature reports of 473 cases from 1922 to 1932 inclusive. There has been an increasing number reported each year, probably because of the larger number of cases, and its more widespread recognition. During this same period there have been reported in Germany approximately 350 cases. The French literature reveals about 100 cases in that country. The disease is apparently quite rare in Russia, Poland, and the Far East, and, for some unknown reason, it is extremely rare in Great Britain. It may be more prevalent in the Far East than we suspect, but the cases probably are not reported.

Dennis<sup>12</sup> has observed two cases in the University Hospital at Beirut, Syria, and states that he discussed the incidence of the disease with several physicians from Palestine and Egypt, and practically all of them had seen cases. Dr. Kleeberg who is practicing in Jerusalem said he had observed the condition there. Up to 1929 there had been only three cases reported from Russia. The rarity of the disease in England is of special significance. It is quite evident that it does not occur in that country to any appreciable extent. As we shall attempt to show, this may have its cause in the type of drugs that are employed by physicians of Great Britain. Briefly stated, granulopenia occurs mainly in the United States and Germany (see Table IV).

TABLE IV  
GEOGRAPHIC DISTRIBUTION OF GRANULOPENIA (FROM 1922 TO 1932)

|               | NUMBER OF CASES |
|---------------|-----------------|
| United States | 473             |
| Germany       | 350 (Approx.)   |
| France        | 100 (Approx.)   |
| England       | 6 (Total)       |
| Italy         | 50 (Approx.)    |

1. The disease is extremely prevalent in Germany and the United States.

2. It is extremely rare in England.

*Age, Sex, and Race.*—A study of Table III reveals the highly significant finding that granulopenia is a disease primarily of the white race, since only eight reports of its occurrence in the colored race were found, and in the

TABLE V  
THE SEASONAL INCIDENCE

| MONTH      | NUMBER OF CASES |
|------------|-----------------|
| January    | 32              |
| February   | 27              |
| March      | 39              |
| April      | 29              |
| May        | 26              |
| June       | 32              |
| July       | 23              |

| December   | 26              |
| Not stated | 159             |

1. There is no apparent seasonal variation.

majority of these, the onset was preceded by arsphenamine therapy. It occurs in the ratio of two females to one male, and this is also true of the cases from other countries. It has no particular seasonal incidence as shown by Table V as cases occur in about equal number throughout the months of the entire year.

The average age is between forty and fifty and ranges from under one year of age to above eighty. It is, therefore, a disease chiefly of middle life.

*Occupation.*—In our studies we have paid particular attention to the occupation of the reported cases and this study has revealed some very interesting and valuable information. It is a striking fact that granulopenia is more prevalent among physicians and their relatives, nurses, hospital employees, and medical students than in any other group of people. Based on the 1930 population census of the United States, it occurs fifty times more frequently in physicians than in lawyers, and two hundred times more frequently in nurses than in female school-teachers. We have made this observation before and have called attention to this singular finding.

It will be noted that of the 200 reported cases in which the occupation is stated, including the housewives, approximately 10 per cent of these have been physicians and members of the medical group. The so-called medical group, including physicians, nurses, hospital employees, etc., constitute 60 per cent of the reported cases of agranulocytosis in the United States in that group in which the occupation is definitely stated. It is not justified to explain this on the belief that this illness is diagnosed more promptly or efficiently in this group of people, since it is well known that physicians are most negligent concerning their own health.

This observation has been noted by several writers. In 1931 Stelhorn and Amolsch<sup>27</sup> in summarizing 42 cases of granulopenia from the region about Detroit, Michigan, made this significant statement, "It is rather curious to note that many of these patients were members of the medical or allied professions, or were relatives of physicians." In their series of cases were 2 nurses, 2 physicians, 1 dentist, and 7 immediate relatives of physicians. Studies of the reports of large series of cases show this same finding to be invariably true. In Harkin's<sup>28</sup> group of 8 cases there was one doctor, one medical student, and one nurse. In a series of about 15 patients from the Mayo Clinic<sup>29</sup> the 2 cases of typical acute fulminant granulopenia occurred in a doctor and a nurse. Hinton<sup>30</sup> and his associates in Macon, Georgia, have studied 6 cases in that section, of which one was a physician and one was a nurse. Sydenstricker<sup>31</sup> reported one case from Augusta, Georgia, who was a physician. Madison and Squier<sup>32</sup> have recently reported from Milwaukee, Wisconsin, a valuable observation, in which they studied 14 patients, of whom 5 were physicians, physicians' wives and nurses, and they stated, "In this group as in the disease at large, there seems to be a most remarkable relation to the medical and allied professions." Fitzhugh and Comroe<sup>33</sup> reported 18 cases from the University of Pennsylvania, and one of them is listed as a physician. Kracke<sup>34</sup> has studied 11 cases around Atlanta, Georgia, in which

there was one physician, one nurse, and one dentist's wife. It is interesting that the only case report we have noted from Poland was one of a physician. Furthermore, we have been advised<sup>12</sup> that 2 physicians are included in the small group of cases around Denver, Colorado.

These observations leave little doubt but that granulopenia is a disease which is peculiar in its relation to the medical profession. Our chief problem then is to determine the possible etiologic factors that could enter into the lives of people in the medical and allied professions that would produce such a large number of cases in this group (see Table VI).

TABLE VI  
STUDIES ON OCCUPATION

|                         |        |
|-------------------------|--------|
|                         | 102    |
| Housewives              | 22     |
| Physicians              | 17     |
| Nurses                  | 4      |
| Maids in hospital       | 3      |
| Medical students        | 1      |
| Laboratory technician   | 11     |
| Relatives of physicians | 2      |
| School-teachers         | 5      |
| Farmers                 | 10     |
| Business men            | 2      |
| Clerks                  | 3      |
| Sailors                 | 1      |
| Dentist                 | 1 each |
| 49 other occupations    | 289    |
| Occupation not stated   |        |

1. The disease is extremely prevalent in physicians and their relatives, nurses, and hospital employees.

2. It is fifty times more prevalent in physicians than in lawyers.

3. It is two hundred times more prevalent in nurses than in female school-teachers.

(Based on population from U. S. Census.)

*Class of People.*—Kracke<sup>14, 23, 34, 35</sup> has repeatedly called attention to the fact that this disease occurs in the better class of our people. In 11 cases in the Atlanta section were included the following: (1) A retired, elderly, cultured woman; (2) a retired, elderly, wealthy woman; (3) a wife of a leading business man in a small town in Georgia; (4) a chief of police in a Georgia city; (5) a wife of an Atlanta dentist; (6) chief librarian in a girls' college; (7) a cultured, refined widow who was economically, moderately well-to-do; (8) the wife of a leading Atlanta architect; (9) a practicing physician; (10) a nurse in the University hospital; (11) a middle-aged white man in the municipal hospital of Atlanta (who was a patient for two months there before developing the disease).

In this connection we quote from the report of Stelhorn and Amolsch<sup>27</sup> as follows: "Very few of the cases occurred among the poor classes. Receiving Hospital, a large hospital maintained by the City of Detroit for the poor, and having an excellent staff of alert, well-read physicians, has no record of any cases of primary granulocytopenia. At least 9 of 31 true cases are extremely well-to-do. Locally the disease is most common among the people of the better classes."

To summarize the peculiar distribution of granulopenia based on our present observations and an exhaustive review of the literature, we would

state: that it is a disease which definitely occurs in the better class of our people; that it has a peculiar predilection for members of the medical and allied professions; that it is confined almost exclusively to the white race; and that it occurs chiefly in Germany and the United States.

#### THE RELATION OF DRUG THERAPY TO GRANULOPENIA

We have long felt that the peculiar distribution of granulopenia could well be correlated with the use of certain benzene containing drugs that are commonly used for therapeutic purposes. We called attention to this in June, 1930, at which time we believed that the benzene ring was incriminated in the production of this disease. At that time we reported our efforts to produce experimentally granulopenia in rabbits using some of the various oxidation products of benzene and using, also, a series of drugs which contained the benzene ring as their nucleus. We have investigated as carefully as possible the various etiologic factors in this respect in eleven cases of true idiopathic granulopenia with the following findings:

CASE 1.—An elderly white woman who had been subjected to repeated cystoscopic examinations over a period of nearly a year, during which time she was given frequently a large number of Peralga tablets (which contain 71 per cent of amidopyrine).

CASE 2.—A middle-aged white woman in whom the onset was preceded by a protracted period of illness diagnosed as influenza, during which time she was given practically daily amidopyrine and empirin compound for a period of several weeks; and prior to that time she had taken about three tablets two or three times a month over the past four-year period.

CASE 3.—A middle-aged white man had taken for more than a year, as much as 15 gr. of amidopyrine daily for attacks of precordial pain, interspersed with a prescription containing phenacetine. Just before the clinical onset he was treated for a condition diagnosed as a mild attack of influenza and was given a prescription of capsules containing phenacetine.

CASE 4.—A middle-aged white woman, the wife of a dentist, had taken a proprietary preparation known as James' Tablets several times weekly over a period of from five to ten years, according to her husband. He stated that his wife took these tablets for every ache and pain. Investigation showed that each tablet contained one grain of acetanilid.

CASE 5.—A young white woman, a nurse in the Emory University Hospital, had taken from 5 to 15 gr. of amidopyrine daily during her menstrual periods for a period of several years and had taken them more frequently during the seven or eight weeks preceding the onset of her illness.

CASE 6.—A middle-aged white woman, librarian, had emotional stress during her last year of life. She was known to have suffered from profuse menstruation and, according to such information as was available, was thought to have been addicted to the use of the so-called coal tar drugs.

CASE 7.—A middle-aged white woman had received three doses of neoarsphenamine and had taken empirin compound for her various minor symptoms (phenacetine, aspirin and caffeine).

CASE 8.—An elderly white woman gave a history of prolonged use of compounds containing phenacetine which had been prescribed for her by her dentist in connection with a long period of dental work.

CASE 9.—A middle-aged white woman had been given phenacetine for five years preceding the onset of her illness, and during this five-year period had taken so much that when she was admitted to the hospital with granulopenia, she presented a typical picture of phenacetine poisoning with the marked slate blue color of sulphhemoglobinemia.

CASE 10.—A middle-aged physician in general practice was known by his brother, who was a dentist, to be a coal tar drug addict, to such an extent, that his brother had even at

times remonstrated that he took entirely too many of these drugs. His brother stated that he had taken such drugs as empirin compound, allonal, pyramidon, etc., almost daily for years for the slightest ache or pain.

CASE 11.—A middle-aged white man admitted to Grady Hospital (Municipal) Atlanta, for treatment of rectal fistula. He was in the hospital for two months during which time his medication covered a wide range of drugs. Included in this were generous doses of pyramidon. It is not known to what extent he took these preparations before his admission to the hospital. It is noteworthy that this patient developed granulopenia only after he had been in the hospital for two months and is the only case of granulopenia that has been observed in the 600 bed Municipal Hospital of Atlanta.

The cases outlined above were of the true idiopathic granulopenic type and do not include the chronic forms.

We have felt for the past three years that members of the medical profession have been prone to prescribe and use this class of drugs for their own ailments and for members of their families. We also feel that the average hospital nurse in the course of her duties, when seeking a mild analgesic, will, because of her familiarity with these newer preparations, employ one of the coal tar drugs instead of the older remedies such as aspirin. We feel also, that average laymen when treating their own aches and pains will use aspirin unless they utilize some drug that has been prescribed for them by their physicians. We have further observed that the average negro who, incidentally, is not subject to as many minor complaints and illnesses as the white person, knows little about this class of drugs and seldom, if ever, uses them on his own initiative.

In order to verify these points, we have conducted a study of several of these groups with particular reference to the usage of the coal tar drugs. This information was obtained by history blanks which were filled out by the following groups of people: (1) 154 student and graduate nurses; (2) 100 physicians; (3) 100 random admissions to the University Hospital (white); (4) 100 admissions to the Municipal Hospital (colored). The results obtained from this series of questionnaires will be seen in Table VII.

To summarize the information from this table, it will be noted that of those nurses who resort to the use of drugs, 76 per cent will select a drug containing the benzamine group; second, of those physicians who will prescribe for themselves and their own families, 56 per cent will use drugs of the benzamine group; third, of the average white lay patients, approximately 27 per cent will select drugs of this class; and, in the colored group about 15 per cent would use this type of drug.

TABLE VII

|                                           | NURSES | DOCTORS | LAITY | NEGROES |
|-------------------------------------------|--------|---------|-------|---------|
| Total number of histories                 | 154.0  | 100     | 100.0 | 100     |
| Total number using drugs                  | 124.0  | 100     | 65.0  | 22      |
| Number using benzamine drugs              | 94.0   | 55      | 17.0  | 15      |
| Percentage using benzamine drugs          | 75.8   | 55      | 26.1  | 15      |
| Number using acetylsalicylic acid         | 26.0   | 45      | 44.0  | 7       |
| Percentage using acetylsalicylic acid     | 20.8   | 45      | 67.9  | 7       |
| Number using drugs not classified above   | 4.0    | --      | 4.0   | --      |
| Per cent using drugs not classified above | 3.3    | --      | 6.0   | --      |

It can be seen, therefore, that there exists almost a direct proportion between the incidence of granulopenia in these groups and the incidence of drug

Fig. 1.—Possible oxidation reactions of the benzamine group of drugs and of benzene.

usage in the same groups. In other words, if a nurse needs an analgesic 3 out of 4 will select a coal tar drug and 3 physicians out of 5 will use the same class of drug, whereas, only 1 white layman out of 4 and 1 negro out of 8

will use the benzamine drugs. We believe, therefore, that there exists a direct relationship between the usage of these drugs to the incidence of granulopenia in these various groups.

The peculiar geographic distribution of granulopenia can also be correlated with usage of this class of drugs. The prevalence of the disease in Germany and the United States approximates the use of coal tar derivatives of this class in these two countries. The practical absence of the disease in England is correlated with the fact that this class of drugs is used to a lesser extent in that country. It is also known that some of these drugs, notably those in combination with barbiturates, have been introduced only within the last ten- or twelve-year period which is the time period of granulopenia. Therefore, based upon these statistical studies and upon our observations in a series of 11 cases of granulopenia and on our studies of drug usage in these various groups of people, we believe that this must be seriously considered as an etiologic factor in this disease.

In October, 1933, Madison and Squier<sup>22</sup> presented a report of 14 cases of granulopenia, and in every instance the onset of the illness had been preceded by prolonged or intensive administration of drugs of this class, and they state, "In each of the 14 cases there was a definite history of amidopyrine in combination with a barbiturate or pyramidon in practically all of the cases we have seen."

On the basis of the evidence submitted in this paper we, therefore, have formulated the hypothesis that the disease owes its high incidence in nurses and physicians to their indiscriminate use of drugs containing the benzamine group, the more prominent members of which are shown in Fig. 1 where the possible mechanism of their oxidation to the intermediate products is graphically illustrated.

It has been shown by repeated animal experiments that the subcutaneous injection of benzene will produce a depression of the bone marrow with a blood picture in which the leucocyte count falls to 200 or 300 cells with complete absence of granulocytes. It is our opinion that this effect is produced, not by the direct action of benzene upon the bone marrow, but by the action of some of its oxidation products. In support of this contention, rabbits were injected subcutaneously with a mixture of equal parts of benzene and olive oil and the tissues at the site of injection were analyzed eighteen hours later for some of these products. The findings showed benzene to be present only in traces, while phenol and catechol were present in considerable amounts. Analysis of a noninjected control animal showed these products to be absent. Similar results with the additional finding of small amounts of hydroquinone have been reported<sup>42</sup> by Schultzen and Naunyn, Munk, Baumann and Herter, and Nencki and Gaicosa. At the same time bone marrow from the injected animals was analyzed and showed the presence of both phenol and catechol but no trace of benzene. Similar control animals gave entirely negative results. This indicated that benzene as such did not reach the bone marrow but did not exclude further oxidation products of the benzene ring as the causa-

It is well known that the presence of an amine group on the benzene ring greatly increases the ease with which the structure can be oxidized. This property is little influenced by the substitution of additional side chains either upon the ring or upon the amine group itself. With these facts in view, we have worked out the possible oxidation products of these drugs in an attempt to arrive at an end-product common to both benzene and the benzamine compounds. These reactions are logical and sound chemically, but are highly theoretical physiologically, in that they have not been proved so to take place in the animal organism.

The oxidation of acetanilid and phenacetine to para-aminophenol both in vitro and in vivo<sup>44</sup> is well established. The compound has been isolated from the urine<sup>45</sup> and the blood serum<sup>46</sup> of patients to whom these drugs have been administered. The further oxidation of para-aminophenol to quinone<sup>47</sup> is easily carried out in vitro, but as yet, has not been demonstrated in animal metabolism. Hydroquinone is probably formed as an intermediate in this oxidation. These reactions are attended by the splitting off of acetic acid in the case of acetanilid, and of acetic acid and ethyl alcohol in the case of phenacetine. The side chains probably are oxidized further as straight chain carbon compounds. The complete reaction is as follows:

The literature affords little information as to the ultimate fate of amidopyrine in normal or abnormal animal metabolism. Current opinion is summed up in the statement that it is excreted either unchanged<sup>48</sup> or as related substances<sup>49</sup> but no mention is made as to what such related substances might be. Chemically, amidopyrine is a pyrazolon derivative of benzene, or it may be looked upon as a derivative of phenylhydrazine, since this compound is used in its synthesis. The presence of the ketone oxygen on the carbon adjacent to the nitrogen makes this linkage extremely unstable<sup>50</sup> so, it is at this point that the pyrazolon ring would break. This gives rise to a straight chain carbon substitution product of phenylhydrazine. The linkage between the two nitrogens of any phenylhydrazine derivative is easily broken by reduction,<sup>51</sup> regardless of the nature of the substituted side chain. This reaction would

give rise to anilin plus a side chain which may be disposed of as indicated in the following reactions. The anilin thus formed is readily oxidized in vitro to para-aminophenol,<sup>44</sup> hydroquinone and finally to quinone, and therefore might undergo the same reaction in the human body. These reactions are as follows:

Several aspects of the toxicity of arsphenamine have been dealt with by Voegtlin.<sup>52</sup> He explains these either on the physical changes that the drug undergoes when injected into the blood stream, or upon the chemical action of trivalent arsenic with glutathione. It is pointed out that this latter reaction upsets the normal tissue oxidation-reduction equilibrium with a resulting tissue asphyxiation. He mentions the occurrence of "aplastic anemias" in some instances, subsequent to the administration of arsphenamine, but does not explain this marrow depression other than by saying that it may be due to the longer retention of arsenic in the bone marrow than in any other tissue.<sup>53</sup> However, our animal experiments in which trivalent arsenic in the form of Fowler's solution was administered over a period of forty days produced no depression.

This lack of action of arsenic tended to center attention upon the benzamine nucleus of the compound. It is well established that arsphenamine or neoarsphenamine when administered intravenously, is readily decomposed by breakage of the double bond between the arsenic atoms, with the resulting formation of two molecules of arsenoxide.<sup>52</sup> According to Voegtlin, it is this compound which, by virtue of its trivalent arsenic, reacts with the SH of glutathione. He also shows that arsenous acid ( $\text{HO}-\text{As}=\text{O}$ ) when administered to animals, is more toxic than either arsphenamine or arsenoxide.<sup>54</sup> This would point to the probability that trivalent arsenic may exert its toxic effect equally well regardless of whether or not it is attached to the benzene ring. Therefore, removal of the arsenic from the ring with its hydrolysis to arsenous acid would leave the benzamine group, ortho-aminophenol, free to

be oxidized to catechol, and finally to ortho-quinone. On the other hand, if arsenic is not split from the ring, the hydroxy and the amine groups can be oxidized, without interference, to the quinone form. This chain of reactions is as follows:

From the above reactions, it is obvious that the progressive oxidation of benzene, acetanilid, phenacetine, amidopyrine, and arspenamine gives rise to several compounds in common. These intermediate and end-products are hydroquinone, catechol, orthoquinone, and para-quinone. It is our belief that one or more of these compounds are responsible for the depressant action of benzene upon the bone marrow, and if so, would point to the benzamine group as also being primary agents in the production of granulopenia.

It must be noted in Table VII that a large percentage of persons in these groups used acetylsalicylic acid in the form of either aspirin or empirin. This compound has as its basis the benzene ring, but no attached amine group. It is well established<sup>55</sup> that this drug is partly hydrolyzed in the gastrointestinal tract to salicylic acid. The unhydrolyzed portion is largely excreted as such, while the salicylic acid is excreted mainly unchanged or conjugated with sulphuric and glycuronic acid. A small portion may be oxidized to oxysalicylic acid and hydroquinone. The amount of this latter product would probably be very small since from a chemical standpoint, the absence of the amine group on the ring would be responsible for the slight degree to which this reaction would take place in comparison to the degree of occurrence of this same reaction in the benzamine drugs.

From a study of the various chemical reactions involved, it becomes apparent that the therapeutic effect of most of these drugs is based on one of the oxidation products. It is also true that the bone marrow depressing effect of benzene is due to one of its oxidation products and not to the drug itself. Therefore, it seems probable that bone marrow depression should be produced by the intravenous injection of one or more of these products.

Up to this time we have been able to produce a mild grade of leucopenia in two laboratory animals with the use of hydroquinone as previously reported.<sup>23</sup> At this time we have injected a large series of animals intravenously with hydroquinone, catechol, aniline, para-aminophenol, quinone and phenol, and we have been able to produce mild and severe grades of neutropenia only in an occasional animal and not to such an extent that we are able to state with certainty that we have reproduced the clinical picture. It must be remembered that all laboratory animals do not have inferior bone marrows, and the same situation may exist in the rabbit as we know exists in the

human being, that is, only an occasional human being develops granulopenia, while many thousands of individuals have taken the benzamine drugs indiscriminately and have shown no depression of the bone marrow.

This can well be illustrated in the case of arsphenamine. As shown by the statistics of the Medical Department of the United States Navy<sup>56</sup> nearly 700,000 doses of neoarsphenamine were administered in the eight-year period from 1925 to 1932, inclusive, with untoward reactions totaling 519, or one reaction in 25,000 doses, with only one bone marrow depression to each 90,000 injections. This is equally true of granulopenia, since only 500 cases have been reported in the United States from a population of 120,000,000 people. Therefore, an inferior, weakened bone marrow must be presupposed in the production of this disease. By the use of various oxidation products, we have been able to depress the leucocyte count of rabbits to as low as 1,000 cells per cubic millimeter. Detailed results of these experiments will be presented in a separate communication.

#### CONCLUSIONS

1. The etiology of granulopenia has not yet been proved.
2. It seems reasonable that a certain percentage of the cases is due to arsphenamine, a certain percentage to gold salts and perhaps other chemicals, leaving, however, a large group of the idiopathic type with an unknown etiology.
3. The disease is more prevalent among physicians and their relatives, nurses, hospital employees and members of the allied professions, than in any other group of people in the United States.
4. It is essentially a disease of the white race.
5. It affects primarily the better class of our people.
6. Its distribution is correlated with the usage of benzamine drugs.
7. A record of 11 cases is presented in which the clinical onset was preceded by prolonged or intensive administration of drugs containing the benzamine group.
8. Statistics are presented to show that this class of drugs has wide usage among members of the medical and allied professions.
9. An hypothesis for its production, based on oxidation reactions of the benzamine drugs, is presented.
10. In the clinical or experimental development of granulopenia, it is necessary to presuppose the existence of a previously weakened, damaged, or idiosyncratic bone marrow which may be congenital or acquired.
11. It is urged that all who have the opportunity to study cases of granulopenia should direct their attention to a careful history of known marrow depressing agents and the usage of benzamine drugs in particular.

## BLOOD IODINE STUDIES\*

### II. THE NORMAL IODINE CONTENT OF HUMAN BLOOD

#### INTRODUCTION

THE constant occurrence of iodine in normal human blood is now firmly established. The ample demonstration of this fact has followed the development of modern micromethods, designed particularly to detect the minute amounts consistently present in clinically obtainable quantities of blood. It is apparent, particularly from the extensive work of Sturm<sup>1</sup> and that of Lunde and his associates,<sup>2</sup> as well as from our own studies,<sup>3</sup> that there is a definite interrelationship between thyroid activity and the blood iodine *niveau*. Furthermore, it is evident that this *niveau* is altered by other physio-

Received for publication, July 18, 1933.

This work has been conducted under a grant from The Douglas Smith Foundation for Medical Research of The University of Chicago.

logic conditions, notably menstruation and pregnancy. There is thus opened up a new approach to studies of thyroid function in health and in disease.

It is evident that it is essential to establish the normal range and average level of the blood iodine in normal individuals, as well as in patients without thyroid disease. Such studies are now available. On the other hand, extensive investigation of the iodine deficiency theory of goiter has led to the conclusion that the iodine intake varies in different regions. Likewise, the manifestations of thyroid disease vary widely in different countries. Too, available iodine, as existing in the food, water, and air, is not the same in various geologic regions. As a consequence it has seemed advisable to make blood iodine determinations of normal individuals in this region; and particularly of our hospital and out-patients without thyroid disease.\* We wish to present in this paper these findings, together with a review of the pioneer work on the blood iodine, and a comparison of our results with those of the more recent studies.

#### HISTORICAL

Baumann's<sup>4</sup> discovery, in 1895, of the presence of considerable iodine within the thyroid gland led to a renewed interest in iodine metabolism as related to thyroid function. Better methods for the determination of iodine were developed, and the blood and other tissues were analyzed for iodine.

The earliest data which we have found for the blood iodine are presented mainly for their historic interest, since they are for the most part at variance with those of the more recent studies. In 1899 Gallard<sup>2</sup> investigated the absorption of iodide by the skin, and its subsequent distribution in the blood and other tissues. He found the iodine content of rabbit blood, after bathing the shaved abdominal skin with sodium iodide solution, to be 635 gamma† per cent. This high value, however, is in accord with other later observations, since it has been shown that the blood iodine rises sharply after iodine administration.<sup>1</sup> In a normal control animal he found 420 gamma per cent. This figure is far too high, in the light of recent studies and of our own work, and indicates contamination, or that the animal had previously received iodine in some form. Gallard used 100 cc. of blood, and a modification of the Rouboudin-Baumann method devised by Bourcet.<sup>6</sup>

Gley and Bourcet,<sup>7</sup> unable to demonstrate iodine in 100 to 200 cc. samples, used a liter of dog's carotid blood to determine the blood iodine. Bourcet's<sup>6</sup> method was followed. They found from 0.013 mg. to 0.112 mg. per liter, or a range of from 1.3 to 11.2 gamma per cent, and an average of 5.5 gamma per cent for the seven dogs. No correlation was observed between the amount of iodine present in the thyroid gland and the blood iodine level. In clotted blood they found the iodine in the serum, and none in the clot. In centrifuged blood the iodine was found only in the plasma. This was not confirmed by Veil and Sturm.<sup>1</sup> Dialysis of the serum or plasma revealed that no iodine

\*The determinations reported at this time are all from the Billings Hospital of the University of Chicago.

†A gamma is the unit used to designate the minute amounts of iodine present in the blood and tissues. It represents one one-thousandth of a milligram (0.001 mg.). The unit has also been designated a microgram.

passed into the dialysate. They consequently concluded that the iodine existed in the plasma in protein combination, and that it was a normal constituent of the blood.

Bourcet<sup>8</sup> investigated the iodine content of other organs and tissues. He found 0.005 mg. of iodine in 200 c.c. of carotid blood pooled from three male rabbits. This is 2.5 gamma per cent. He also found small quantities of iodine in dog's blood. In studying iodine elimination, he examined human menstrual blood. In five individuals this contained from 0.80 to 0.90 mg. of iodine per kilo of blood, or 80 to 90 gamma per cent. In a sixth woman simultaneous epistaxis blood was examined. The menstrual blood contained 94 gamma per cent of iodine, the epistaxis blood contained but 2.1 gamma per cent. He consequently concluded that menstrual blood is an important vehicle of iodine elimination, owing to its high iodine content.

Gley and Bourcet<sup>9</sup> subsequently investigated the effect of exsanguination on the blood iodine of male dogs, using from one-half to one liter of arterial blood. In six normal animals the blood iodine ranged from 2.8 to 9.8 gamma per cent, averaging 7.5 gamma per cent. In two others extreme values were found, 300 gamma per cent in one and less than 1 gamma per cent in another. They found that the blood iodine diminished rapidly after extensive exsanguination, and that after several days, it disappeared completely from the blood. These results are open to serious question.

Blum<sup>10</sup> sought to determine whether the specific "Jodeiweiss" of the thyroid was secreted into the blood stream. He regarded the thyroid as essentially an organ of intraglandular detoxication. In accord with his view the iodine, which Baumann had demonstrated to be present, might be used only in the local economy. With Grützner,<sup>11</sup> a method was devised and tested for the determination, by titration, of organically combined iodine in the presence of organic matter. The "inorganic" iodine was first extracted by acetone. This method was first applied to sheep's blood.

Blum and Grützner<sup>12</sup> subsequently attempted to answer the question of the constant presence of thyroid secretion, as organically combined iodine, in the blood. Using Hunter's<sup>14</sup> method on 50 to 1340 c.c. samples of whole blood, they found from 14 to 140 gamma per cent in five male sheep. However, in four others they failed to detect iodine. They likewise found none in two 125 c.c. samples of goat's blood. Using their own method<sup>11</sup> they detected iodine ("inorganic") but twice in the acetone extract of 6 samples of sheep's blood, and found none at all in the residual coagulum. Likewise no iodine was detected in the blood of 3 dogs, in the blood of 2 men, or in the blood of 2 pregnant women. In the blood of 5 dogs, "jodfrei ernährte," no iodine was found, even though the thyroids contained considerable iodine. They consequently doubted the existence of iodine as a normal constituent of the blood. After giving from 0.5 to 2.0 gm. of sodium iodide to 6 dogs, the blood constantly contained iodine, even up to twenty days after the administration. This was found in the acetone filtrate ("inorganic").

Pathologic bloods were then examined. Unfortunately they were unable to obtain and analyze the blood of patients with exophthalmic goiter, whose blood iodine was subsequently discovered<sup>1</sup> to be high. Among 16 patients

with eclampsia, 10 showed from a trace to 100 gamma per cent of organically combined (coagulum) iodine. Iodine was similarly found in the blood of 2 patients with severe nephritis and in one with convulsions due to a brain tumor. They concluded that iodine in organic combination does not occur in normal blood, and that the "inorganic" iodine occasionally found, comes from the food ingested, or from medication.

Cameron<sup>13</sup> made an extensive investigation of the iodine content of various plant and animal tissues. He used Hunter's method.<sup>11</sup> He found no iodine in dog or rabbit blood, nor in many other tissues. The sample, 0.5 gm., taken for analysis, however, was too small, in view of the minute amount of iodine normally present and the sensitiveness of the method he employed. It would be difficult to demonstrate the presence of iodine in 0.5 gm. of blood even by the most sensitive modern methods.

These pioneer investigations had shown that iodine may be detected by using sufficient amounts of normal mammalian blood and by employing adequate methods. A number of significant questions had thus been raised, among them: Is iodine a constant constituent of mammalian blood? If so, in what combination does it exist—organic, inorganic, or both? What is its relation to the thyroid gland, and to the thyroid iodine? What is its relation to thyroid disease? The answer to these, as well as further progress, was dependent upon the development and application of more sensitive methods for the biochemical determination of iodine.

"The first modern figure for blood iodine," as Orr and Leitch<sup>15</sup> are pleased to term it, is that of Kendall and Richardson<sup>16</sup> for ox blood, 13 gamma per cent.\* Kendall's method<sup>17</sup> was used on 100 c.c. samples. In twenty-three analyses, the level ranged from 10 to 17 gamma per cent, averaging 13 gamma per cent. In sixteen subsequent analyses, known amounts of iodine were added to the water solution after charring and fusing the blood. The amount added was subsequently subtracted from that determined. The range in these was from 4 to 21 gamma per cent. The average, however, was the same, 13 gamma per cent. When known amounts of iodine were added to whole blood, from 2.2 to 3.0 per cent was not recovered by the analysis. The lower limit of detectable iodine by Kendall's method is about 5 gamma (0.005 mg.).

Gley and Cheymol, observing that the goat thyroid contained considerable iodine,<sup>19</sup> examined the efferent blood from the thyroid veins of eight female goats.<sup>18</sup> In this manner they attempted to demonstrate the passage into the blood of the iodine-containing thyroid secretion. Kendall's method was used on 100 c.c. samples. The carotid blood was found to contain from 4.3 to 26 gamma per cent, averaging 12.3 gamma per cent. Efferent thyroid blood, however, was found to contain from 5 to 50 gamma per cent, averaging 20.8 gamma per cent. They consequently concluded that they had demonstrated the passage of the internal secretion of the thyroid into the blood stream. No correlation was observed between the varying iodine content of the thyroid gland and that of the efferent blood.

\*This is variously quoted in the literature as for human or dog blood. Kendall<sup>16</sup> used ox blood for the determinations. A large series of determinations were also made on human and dog blood. The values were all within a narrow range.

Cheymol and Gley,<sup>20</sup> using Kendall's method, found 13 gamma per cent of iodine in the pooled blood from 5 male guinea pigs, and 11 gamma per cent in the pooled blood of 5 females. In dog's carotid blood they found 9.6 gamma per cent, and in the blood of the female goat 12.4 gamma per cent. Samples of 100 c.c. were used for analysis.

#### RECENT INVESTIGATIONS

During the first decade of the twentieth century advancing goiter research had created a demand for an adequate method for the determination of minute amounts of iodine. In 1922 the Swiss Goiter Commission consequently requested von Fellenberg, of the Government Bureau of Hygiene, to develop such a method. He devised, perfected, and eventually synthesized the known existing quantitative procedures into a true micromethod for the determination of iodine.<sup>22</sup> The lower limit of detectable iodine by this method is about one ten-thousandth of a milligram (0.0001 mg.). Two of his pupils, Sturm and Lunde, soon applied his method to the study of the blood iodine in thyroid disease.

The successful application of the principles developed in von Fellenberg's method has led to such extensive developments that from this point we must limit ourselves to the discussion of normal human blood iodine values. Since determinations of the blood iodine on hospital patients have been used by some investigators as normal, we are including them in this report. However, we are omitting all blood iodine reports on goitrous patients, on patients with dietary deficiency diseases, on patients with acute inflammations, and on those with leucemia, as well as blood iodine determinations made on women during early menstruation, pregnancy, and lactation.

Alexander Sturm learned von Fellenberg's method at Berne. Returning to Veil's Clinic in Munich, he investigated extensively the blood iodine in normal individuals, in patients with thyroid disease, and in those with various other diseases. His study<sup>1</sup> presented, in 1925, the first comprehensive data of normal human blood iodine values. In a series of 36 individuals, studied in the late summer and fall, the blood iodine averaged 12.8 gamma per cent. In 24 normal individuals investigated during late fall and winter the average was lower, 8.3 gamma per cent. The iodine occurred in similar concentration in the plasma and in the corpuscles. When the blood proteins were precipitated by alcohol, about 35 per cent of the iodine was recovered in the alcoholic filtrate. The remaining 65 per cent was found in the precipitate. From Jena, in 1928, Sturm<sup>23</sup> reported a series of blood iodine determinations made on 10 men. These revealed high values in May and July, of 15.0 and 14.1 gamma per cent, respectively. The lowest level, found in December, was 9.9 gamma per cent.

Maurer and Diez,<sup>24</sup> of Munich, investigated the blood iodine during menstruation and pregnancy. During this study they determined the blood iodine of 10 women during the intermenstrual period. These determinations were made during the winter. They ranged from 4.2 to 15.0, averaging 9.2 gamma per cent. Later, Jahn and Kesselkaul,<sup>25</sup> also of Munich, studied the variation of the blood iodine during the menstrual cycle. They reported that 17 normal

women had intermenstrual blood iodine values ranging from 7.2 to 12.0 gamma per cent, and averaging 9.5.

Jansen<sup>26</sup> reported an average of 12 to 14 gamma per cent in normal individuals at Bonn.

In the study which DeQuervain and Smith<sup>27</sup> made at Berne, on the blood iodine of cretins and of patients with nontoxic nodular goiter, they included a series of determinations made on five normal individuals during the winter. These determinations ranged from 11.1 to 14.6 gamma per cent, with an average of 13.1.

Lunde, Closs and Pedersen,<sup>2</sup> reported 11 to 16 gamma per cent as the normal blood iodine level occurring in Oslo. For fractionating the blood iodine, Lunde devised a method of alcohol extraction. This differs from Sturm's<sup>1</sup> method of alcohol precipitation. By Lunde's method only 1 to 4 gamma per cent was found in the alcohol insoluble fraction. Work from Lunde's laboratory indicates that the alcohol insoluble fraction is of particular significance in the pathologic physiology of toxic goiter.

At Aberdeen, Orr and Leitch<sup>15</sup> determined the blood iodine by the Leitch and Henderson method. They found in 16 normal individuals, examined in the spring, an average of 6 gamma per cent, while that of 28 individuals, examined in the fall, averaged 8.4.

In 1929 Eisler and Schittenhelm,<sup>28</sup> using the von Fellenberg method, reported from 10 to 13 gamma per cent as the normal blood iodine level for Kiel. The same investigators in 1932,<sup>29</sup> reporting seventy-one blood iodine determinations, gave from 7 to 9 as the range for winter and from 9 to 12 as the range for the summer.

Fowweather,<sup>30</sup> while studying the blood iodine in patients with cancer, estimated the blood iodine in twelve normal individuals. He found a range of from 3.6 to 5.1 gamma per cent, with an average of 4.3. This investigation was made at Leeds, using the Leitch and Henderson method.

Baldauf and Pincussen,<sup>31</sup> who studied the interrelationship between the bromine and iodine concentration of the blood, reported an average of 10.9 gamma per cent for a series of blood iodine determinations made on normal individuals in Berlin. Scheringer,<sup>32</sup> also in Berlin, in a series of 9 individuals studied between January and July, found from 6 to 15 gamma per cent, with an average of 8 gamma per cent. The following year he reported<sup>33</sup> another group of 8 individuals with a range of 10 to 13. Twelve of Scheringer's 17 subjects were women and the intermenstrual values were taken as the normal for them.

In 1930 Turner,<sup>34</sup> of Detroit, reported 9 cases on which he found a range of from 9 to 15, and an average of 11 gamma per cent. He used his own method for the determination of the blood iodine.

Schneider and Widmann,<sup>35</sup> of Freiburg, used von Fellenberg's method on 15 patients, 5 normal subjects and 10 nongoitrous patients. They found the blood iodine to range from 8.2 to 17.5 gamma per cent, with an average of 12.5. A year later Widmann<sup>35</sup> used his own modification of the Schwaibold

closed oxidation procedure for blood iodine on 6 nongoitrous patients. He found blood iodine values ranging from 27 to 42 gamma per cent, with an average of 32. This modification needs further investigation to rule out the possibility of other oxidizing substances than iodine containing radicles being carried over in the oxidation process, and later reacting with the added potassium iodide.

Billmann<sup>37</sup> found a range of 8 to 18 gamma per cent in 10 individuals. The patient on whom Bøe and Elmer<sup>38</sup> studied the effect of intravenous thyroxin administration had a normal blood iodine of 12 gamma per cent.

An extensive study of the blood iodine fractions in normal subjects was reported from Paris by Nitzescu and Binder.<sup>39</sup> Their investigations were made on a group of healthy male subjects ranging in age from twenty to thirty years. The lowest average blood iodine, 8.7 gamma per cent, was found in 47 cases studied in February. The highest averages were found in June, 12.7 for 16 cases, and in July, 12.9 for 11 cases. The average inorganic fraction ranged from 2.2 gamma per cent in January to 5.1 gamma per cent in June, while the organic fraction was lowest in February at 6.1 and highest in July at 8.1 gamma per cent. There was thus a greater variation in the inorganic than in the organic fraction. The separation was carried out according to Lunde's procedure. In this determination the "organic" fraction contains all of the alcohol insoluble fraction plus the "organic" portion of the alcohol soluble fraction.

While studying the relationship of the iodine concentration in the blood to that in the cerebrospinal fluid, Hahn and Schurmeyer<sup>40</sup> found in 17 individuals a range of 7 to 14 gamma per cent, with an average of 10.6.

Dodds, Lawson and Robertson,<sup>41</sup> working in London and using Lunde's method, found in 7 normal subjects under forty years of age, an average of 10.2 gamma per cent with a range of from 7.8 to 17.6. The alcohol soluble fraction in the 7 varied from 4.9 to 11.9 gamma per cent, with an average of 7.7. The alcohol insoluble fraction in 16 cases varied from 2.4 to 5.8 gamma per cent, with an average of 4.

#### OBSERVATIONS .

The blood iodine determinations here reported were all made by Davis<sup>42</sup> method. This is a development of the von Fellenberg procedure. The results obtained are best presented in tabular form (Tables I, II and III).

In Table I is presented a series of 8 determinations made on 6 normal members of the Billings Hospital staff. The determinations on the women were all made during the intermenstrual period. These individuals were all taking the usual hospital diet, which contains no iodized salt. The range of the 8 determinations is between 8.9 and 13.8, and the average 12 gamma per cent.

In Table II is presented a series of 13 determinations made on 10 hospital patients. The diagnoses are given. None of these patients revealed evidence of thyroid disease. All were under careful observation, and on controlled diets which contained no iodized salt. The age range is wide, from thirteen

to seventy-eight years. The blood iodine ranges from 8.5 to 14.4, averaging 12.3 gamma per cent. In accord with Fowweather<sup>30</sup> we observe that the presence of cancer has no obvious effect upon the level of the blood iodine.

greater. This may be due to the fact that there was no dietary control and that certain of the bloods were not drawn in the postabsorptive state.

In all, 34 determinations made on 28 individuals without evidence of thyroid disease revealed a range of from 8.5 to 16.2 and an average of 11.9 gamma per cent. It would thus appear that about 12 gamma per cent is the normal average blood iodine level in Chicago.

The 18 determinations made upon women ranged from 8.5 to 16.2, averaging 11.6 gamma per cent. The 16 determinations made upon men ranged from 9.5 to 14.4, averaging 12.2 gamma per cent. The greater range of the female levels is presumably to be associated with the cyclic variations in the blood iodine due to menstruation. The male average level is slightly higher.

#### DISCUSSION

The results of available studies upon the normal blood iodine are presented in Table IV. Omitting the very low results of Fowweather<sup>30</sup> and the very high results of Widmann,<sup>31</sup> the average normal levels for the blood iodine vary from 6.0 to 13.1 gamma per cent. Since iodine loss is the most important single factor in making the determinations by the open oxidation methods, we are inclined to regard those results at the upper range as more nearly the true condition. A study of the table would lead us to conclude that the blood iodine in normal individuals, or in patients with normal thyroid function, is only influenced slightly, if at all, by geographic location.

The seasonal variation of the blood iodine is of interest. It corresponds to that observed in the thyroid gland by Seidell and Fenger.<sup>13</sup> A tabulation of available data readily shows a confirmation of the results first announced by Veil and Sturm,<sup>1</sup> that the highest values are obtained in the summer months and the lowest in the winter.

The fractionation of the blood iodine into an alcohol or acetone soluble, and an insoluble fraction is doubtless of significance. We have not yet attempted this procedure. It is apparent that the alcohol insoluble fraction is approximately the same when the determination is consistently made by the same method. It varies greatly, however, with the mode of extraction. The work of Lunde and his associates on the blood iodine in hyperthyroidism points to the significance of the alcohol insoluble fraction. Presumably it is the thyroid hormone. The "inorganic" iodine may come from the diet or from catabolism of the "organic" iodine compounds.

#### SUMMARY

Iodine is constantly present in the human blood. The average level is about 12 gamma per cent. Development of our knowledge regarding this fact followed the institution of adequate micromethods for the determination of the minute amounts normally present. The blood iodine varies seasonally, being higher during the summer and lower during the winter months. The blood iodine may be separated into "organic" and "inorganic" fractions. Determinations of the blood iodine open up a new approach to the study of thyroid function in health and in disease.

KINSMAN HALL, OHIO STATE UNIVERSITY

## THE SEDIMENTATION RATE AND POLYMORPHONUCLEAR COUNT IN RHEUMATOID AND MIXED ARTHRITIS\*

THEIR VALUE AS AN INDEX TO ACTIVITY

WILLIAM B. RAWLS, M.D., F.A.C.P., BENJAMIN J. GRUSKIN, M.D., ANTHONY A.  
RESSA, M.D., AND MARIE JORDON, B.S., NEW YORK, N. Y.

THE sedimentation rate and the polymorphonuclear count (hereafter referred to as the nuclear count) have been applied in the study of a number of different diseases, but it has been only during the past few years that they have been used in the study of arthritis. A number of papers have been published on the value of the sedimentation rate in arthritis but comparatively few have appeared on the nuclear count.

Various investigators<sup>1, 2, 3, 4</sup> have stated that the sedimentation rate is greatly increased in rheumatoid arthritis while in osteoarthritis the rate is usually normal or only slightly increased. It has been used mostly as an aid in differentiating these two types of arthritis. It has been reported<sup>3</sup> that there is a close relationship between the sedimentation rate and the severity of the infection; that remissions are associated with a decreased rate and exacerbations with an increased rate. Some<sup>5, 6</sup> have suggested that this test may be of assistance in following the progress of the patient's illness. They have not, however, reported the frequency with which these changes occur. Kahlmeter<sup>1</sup> suggested the use of the sedimentation rate as an index of activity, a knowledge of which he believes to be essential for the proper use of physiotherapy. Forestier<sup>4</sup> has shown that as the patient improves, the sedimentation rate returns to normal.

The value of the nuclear count is based on the observation that an active infection is accompanied by an increase in the number of young polymor-

Received for publication, August 29, 1933.

phonuclear neutrophils in the blood. An increase in the number of these cells is termed "shift to the left." Only recently has this principle been used in the study of arthritis. Schilling<sup>7</sup> stated that in rheumatoid arthritis only slight changes are present in the hemogram, but other investigators using the Schilling hemogram have reported more conclusive findings. Cecil<sup>8</sup> reported a shift to the left in 52 per cent of 23 cases of rheumatoid arthritis and that Resnikoff found a shift to the left in 67 per cent of 28 cases. Eaton<sup>9</sup> in his study of 250 cases of chronic nontuberculous arthritis found a shift to the left in 90.4 per cent. Gerard and Boerner<sup>10</sup> reported two cases, and Piney<sup>11</sup> one, of arthritis with a shift to the left. Recently, Steinbrocker and Hartung,<sup>12</sup> using the filament nonfilament count, a modification of the Schilling hemogram advocated by Farley, St. Clair, and Reisinger, reported finding what is the equivalent of a shift to the left in 100 per cent of 50 cases of rheumatoid arthritis.

The present study was undertaken to determine whether exacerbations and the periods of improvement in patients with rheumatoid and mixed arthritis are accompanied by definite changes in the sedimentation rate and the nuclear count and the relationship between the two tests. We chose for our study a group of patients who attended the clinic regularly. At each visit a detailed record of both the subjective complaints and the objective findings was made. The presence of any intercurrent infections was also noted. Whenever there was a change in the condition of the patient, the sedimentation rate and nuclear count were determined. In a number of instances these determinations were made when there was no change in the patient's condition. They were always made at approximately the same time of the day. Westergren's<sup>13</sup> modification of Fahraeus' technic was used for the sedimentation, and a rate of 12 mm. or less per hour was considered normal. In making the nuclear counts, the technic of Cooke and Ponder<sup>14</sup> was used. Farley, St. Clair, and Reisinger,<sup>15</sup> in reviewing the work of Arneth, Schilling, and Cooke and Ponder, state that the classification of Arneth is too complicated for practical use, and that the method of Schilling lacks the clear-cut differentiation which can be obtained by following Cooke's criterion. This criterion is as follows: "If there is any band of nuclear material except a fine filament of nuclear material connecting the different parts of a nucleus, that nucleus for the purpose of the count cannot be said to be divided." With this as a basis, the polymorphonuclear neutrophils were divided into five groups according to the number of segments. In determining the presence or absence of a shift to the left, Cooke and Ponder considered as an average normal count, 12 Type I, 25 Type II, 44 Type III, 15 Type IV, and 4 Type V cells per 100 polymorphonuclear neutrophils.

In the early part of this work we failed to realize the importance of intercurrent infections, but as the work proceeded we excluded all those tests which were made when the patient was suffering from such infections. Determinations were made in 50 cases each of rheumatoid and mixed arthritis. A total of 262 sedimentation tests were done in the former and 234 in the latter group. Of the patients with rheumatoid arthritis 89 per cent had a

sedimentation rate above normal. The average rate was 36 mm. per hour. In 53 per cent of the tests the values were above 30 mm. per hour. Of the 234 determinations in mixed arthritis, 64 per cent were above normal. The average rate in this group was 18 mm. per hour with only 15 per cent of the cases showing values above 30.

Of 258 nuclear counts made on 50 patients with rheumatoid arthritis, 68 per cent showed a shift to the left. In 23 per cent the counts were within normal limits and in 9 per cent there was a slight shift to the right. In the cases of mixed arthritis, 244 counts were made, of which 57 per cent showed a shift to the left, 36 per cent presented normal counts and 7 per cent showed a shift to the right.

In 210 instances in the rheumatoid group the sedimentation rate and the nuclear count were compared. In 77 per cent a shift to the left was associated with a high sedimentation rate. In 10 per cent there was a normal sedimentation rate and either a shift to the right or a normal count. In 6.5 per cent there was a normal count or a shift to the right accompanied by a high sedimentation rate, and in 6.5 per cent there was a shift to the left with a normal sedimentation rate. In the series of mixed arthritis, 190 comparisons were made. Of these, 58 per cent presented both a shift to the left and a high sedimentation rate, while 14 per cent showed a normal sedimentation rate and either a normal count or a shift to the right. In 23 per cent of the cases in this group, a shift to the left was accompanied by a normal sedimentation rate, and in 6 per cent there was a high sedimentation rate contrasted with either a normal count or a shift to the right (Table I).

TABLE I  
CORRELATION OF THE SEDIMENTATION RATE AND THE NUCLEAR COUNT

|                                                   | RHEUMATOID<br>PER CENT | MIXED<br>PER CENT |
|---------------------------------------------------|------------------------|-------------------|
| High sedimentation rate<br>Shift to the left      | 77.0                   | 58                |
| Normal sedimentation rate<br>Normal nuclear count | 10.0                   | 14                |
| High sedimentation rate<br>Normal nuclear count   | 6.5                    | 6                 |
| Normal sedimentation rate<br>Shift to the left    | 6.5                    | 22                |

In 274 instances the sedimentation rate, the nuclear count and the clinical condition of the patients were simultaneously recorded in order to study the value of these tests as an index to activity. In this group no differentiation was made between the rheumatoid and mixed cases. Of the total number, 119 were made when there was improvement in the clinical symptoms, 56 when they were worse, and 99 when they were unchanged. Of the 119 made during clinical improvement, 74 per cent showed a definite reduction in both the sedimentation rate and the degree of the shift to the left; 6 per cent showed a slight increase in the sedimentation rate and a further shift to the left; 9 per cent showed no change in either the sedimentation rate or the nuclear

count; 6 per cent showed no change in the nuclear count but a reduction in the sedimentation rate; 3 per cent showed an approach to normal in the nuclear count but no change in the sedimentation rate; 2 per cent showed an approach to normal in the nuclear count and a slight increase in the sedimentation rate. Of the determinations made when there was an exacerbation of the clinical symptoms, 65 per cent showed an increase both in the sedimentation rate and in the degree of the shift to the left, while 14 per cent showed a slight reduction in both. In 14 per cent there was an increase in the sedimentation rate but a decreased shift to the left; in 7 per cent there was no change in the nuclear count but a slight reduction in the sedimentation rate. Where the clinical condition was unchanged, 49 per cent showed no change in either test. In 24 per cent there was a slight reduction in the sedimentation rate and in the shift to the left; 4 per cent showed a slight reduction in the sedimentation rate and an increased shift to the left; 6 per cent showed a slight increase in the sedimentation rate and in the shift to the left; 3 per cent presented a slight increase in the sedimentation rate but no change in the nuclear count; 3 per cent showed no change in the sedimentation rate but a decreased shift to the left; 3 per cent gave an increased sedimentation rate and a decreased shift to the left; 3 per cent gave no change in the sedimentation rate but an increased shift to the left, and 5 per cent gave a decreased sedimentation rate and no change in the nuclear count. (Table II.)

TABLE II  
CHANGES IN THE SEDIMENTATION RATE AND THE NUCLEAR COUNT CORRELATED WITH  
CHANGES IN THE CLINICAL CONDITION

| SEDIMENTATION RATES AND NUCLEAR COUNTS | CLINICAL CONDITION   |                   |                       |
|----------------------------------------|----------------------|-------------------|-----------------------|

## DISCUSSION

Although several articles have been published on both the sedimentation rate and the nuclear count in arthritis, there have been no reports of a correlation of the two tests and their value as indicators of activity. They have been used mainly as an aid in the differential diagnosis between rheumatoid and osteoarthritis. Our study indicates that these tests are of considerable value as an index of the activity of the arthritic process in patients with rheumatoid and mixed arthritis and as such are efficient aids in judging the progress of the patient. When the clinical condition is improved, there is usually a decrease in the sedimentation rate and a lessened shift to the left. Conversely, an increase in the severity of the arthritic process is associated with a rise in the sedimentation rate and a further shift to the left. The degree of change in these tests is fairly proportionate to the degree of change in the clinical condition. On numerous occasions we noted that intercurrent infections, such as colds and sore throats, adversely affected the sedimentation rate and nuclear count, and they, therefore, must be excluded before attributing changes in the tests to changes in the course of the disease. In the absence of any infection, however, the sedimentation rate and nuclear count tend to return to normal when the clinical symptoms have subsided. We have also observed that a hidden focus of infection will frequently give a persistent, high sedimentation rate and a shift to the left.

## CONCLUSIONS

1. In the majority of cases of rheumatoid and mixed arthritis the sedimentation rate and the nuclear count serve as an index of activity, and they may, therefore, be used as a means of determining the progress of these diseases.
2. The degree of change in the clinical symptoms is reflected in parallel changes in the sedimentation rate and nuclear count.
3. Intereurrent and focal infections adversely affect the sedimentation rate and nuclear count, and their presence must be excluded before changes in these tests may be attributed to variations in the activity of the arthritic process.
4. The variations in the sedimentation rate and the nuclear count do not correspond 100 per cent to the variations in the arthritic state, and therefore, neither alone is finally diagnostic; and knowledge of both the sedimentation rate and the nuclear count together should increase the accuracy of the interpretations.

## THE BACTERICIDAL AND FUNGICIDAL ACTION OF HOMOLOGOUS HALOGEN PHENOL DERIVATIVES AND ITS "QUASI- SPECIFIC" CHARACTER\*

---

### I. DERIVATIVES OF PARACHLOROPHENOL

### INTRODUCTION

IN TWO recent papers<sup>1</sup> we described the preparation of a number of halogen phenol derivatives with bactericidal properties, giving also a survey of published work which preceded our investigations in this field. While all the derivatives studied by us were found to be germicidal toward a number of microorganisms among which were several resistant pathogenic bacteria and fungi, some of them were shown to possess this capacity to a remarkably high degree. In following up the relationship between the chemical structure and the bactericidal action of these compounds we observed a number of regularities, viz.:

1. Halogen substitution intensifies the microbicidal potency of phenol derivatives, the presence of halogen in the para-position to the hydroxyl group being more effective in this respect than in the ortho-position.

2. Introduction of aliphatic or aromatic groups into the nucleus of halogen phenols increases the bactericidal potency (up to certain limits), this increase depending, in the case of alkyl substitution, upon the number of carbon atoms present in the substituting group or groups.

3. As a rule the intensifying effect upon the bactericidal potency of a normal aliphatic chain with a given number of carbon atoms is greater than

---

\*From the Plaut Research Laboratory, Lehn & Fink, Inc.  
Received for publication, July 27, 1933.

that of a branched chain, or of two or more alkyl groups with the same total number of carbon atoms.

4. Orthoalkyl derivatives of parachlorophenol are more actively germicidal than paraalkyl derivatives of orthochlorophenol.

5. In the case of the higher homologues the germicidal action manifests a "quasi-specific" character in that beginning with a definite point (which is different in the case of the various test organisms), with the further increase of the weight of the substituting groups, the germicidal capacity drops to almost total inactivity with respect to certain microorganisms (*Eberthella typhi*, *Eberthella paradysenteriae*), while rising to comparatively enormous values with respect to others (*Staphylococcus aureus*, streptococcus, *Mycobacterium smegmatis*).

It is the object of further work to extend the scope of our inquiry into the bacteriologic and pharmacologic phases of this problem, with the ultimate view of ascertaining the possible utility of these compounds for therapeutic purposes. The present paper furnishes the data obtained thus far with compounds derived from parachlorophenol; these compounds may be represented by the general formula

where R is an aliphatic or aromatic substituent.

The following microorganisms were used in this investigation: *Eberthella typhi*, *Escherichia coli*, *Eberthella paradysenteriae* (Flexner), *Salmonella schottmülleri* (*B. paratyphosus B*), *Staphylococcus pyogenes aureus*, streptococcus (hemolytic strain), *Micrococcus catarrhalis*, *Mycobacterium smegmatis*, *Mycobacterium tuberculosis* (hom.), *Mycobacterium tuberculosis* (avium), *Mycobacterium leprae* (mur.), *Mycobacterium leprae* (hom.), *Trichophyton roseaceum*, *Monilia albicans*, and *Achorion schönleinii*.

#### MONOALKYL DERIVATIVES

Tables I to IV illustrate the microbicidal action of the series of monoalkyl derivatives of parachlorophenol in relation to their chemical constitution, and more particularly to the increase in length (or weight) of the substituting side chain. Wherever possible, the minimum germicidal concentrations have been determined and the "phenol coefficients" calculated. Table I gives the results obtained with four gram-negative organisms of the typhoid colon group, in Table II the test organisms are (gram-positive and gram-negative) cocci, in Table III they are bacteria of the acid-fast group, while Table IV refers to three pathogenic fungi.\*

When considered individually, certain among the several compounds reveal a bactericidal effect of considerable intensity. However, in addition there is also unmistakable evidence of a parallelism in both a qualitative and

\*The figures given in parentheses are of relative significance only, as alcohol in excess of 10 per cent but below 20 per cent had to be used in order to produce the desired concentrations (owing to the very limited solubility of the respective compounds).

quantitative respect in the reaction toward the homologues of this series, of the microorganisms in Table I on one hand, and of those in the remaining three tables on the other.

Thus, in Table I the bactericidal efficacy rises with the increasing weight of the substituting side chain reaching a maximum with the n-butyl derivative in the case of *Salmonella schottmülleri*, and with the n-amyl derivative in the cases of *Eberthella typhi* and *Escherichia coli*, while the n-hexyl derivative is the most effective against *Eberthella paradysenteriae*. After reaching the maximum, one observes a rather abrupt drop of the bactericidal potency with the further increase of the weight of the substituents.

In agreement with observations made with other classes of phenol derivatives, here, too,<sup>2, 3, 4</sup> substitution by branched or cycloalkyl groups leads to compounds of lower bactericidal potency than that of the normal alkyl derivatives with the same number of carbon atoms in the substituting group.

An entirely different picture is furnished by Table II. Here, too, the coccidal potency increases with the increasing weight of the substituting radical, but its range extends beyond the turning points of the preceding table.

TABLE II

THE GERMICIDAL ACTION OF ORTHOALKYL DERIVATIVES OF PARACHLOROPHENOL UPON PATHOGENIC COCCI.

| Phenol (control) | 1:70-80                  | 1.0     | 1:80-90                          | 1.0     | 1:140-160                  | 1.0    |

While the cocci show greater resistance to the unsubstituted parachlorophenol and its lower homologues than the typhoid colon organisms (as evidenced by the higher concentrations required to kill the former), the conditions are reversed with the further increase of the molecular weight; now the coccidal efficiency increases until in the case of the n-heptyl derivative, the three cocci are killed in extremely low concentrations which, like the corresponding phenol coefficients, belong to an order of magnitude much higher than that of the preceding table. While the n-octyl p-chlorophenol is more effective against *Staph. aureus* than the n-heptyl derivative, its potency is less than that of the latter with respect to the other two cocci of Table II. It is to be noted especially that the greatest coccidal potency is shown by those derivatives which exert little or no effect upon the four organisms of the colon typhoid group previously referred to (Table I).

The susceptibility of the acid-fast bacteria (Table III) to the action of the monoalkyl homologues of parachlorophenol resembles that of the cocci in Table II both in a qualitative and a quantitative sense. The extraordinarily great bactericidal efficacy of the higher homologues against the organisms of the acid-fast group is particularly noteworthy in view of their reputed resistance to the action of phenolic disinfectants.

The "quasi-specific" feature of the germicidal action of the higher homologous orthoalkyl parachlorophenols has a parallel in the differentiation of

Chart 1.—The germicidal action of orthoalkyl derivatives of parachlorophenol. Test organisms: I, *Eberthella typhi*; II, *Staphylococcus aureus*; III, *Mycobacterium tuberculosis* (hom.); IV, *Monilia albicans*.

bacteria by means of the Gram stain and also in the action of certain basic dyes upon bacteria.<sup>5, 6</sup> More particularly, it appears that a gram-positive character and a susceptibility to the homologues with a higher molecular weight, run parallel in most but not in all cases. Thus *Micrococcus catarrhalis* forms an exception, in that in spite of its negative Gram reaction, it behaves much like the gram-positive organisms in this respect. However, it shows a similar behavior toward certain dyes. By way of advance information, it may be stated that *Vibrio cholerae* reacts essentially in the same manner to the higher homologues of this and other series of phenol derivatives, in spite

of its gram-negative character. Thus, while there are several examples of gram-negative microorganisms behaving like those of a positive Gram character in regard to their selective susceptibility to the "quasi-specific" action of the higher homologues of "phenolic" compounds, we do not know, to date, of any case of a gram-positive microorganism behaving under these conditions like the gram-negative bacteria of the typhoid colon group.

In spite of the entirely different morphologic character of the pathogenic fungi dealt with in Table IV, one is confronted again by the regularity in the functional reaction between the chemical constitution and fungicidal action, and by the somewhat astonishing qualitative and quantitative resemblance of this relation with that observed in the case of the cocci in Table II and of the acid-fast bacteria in Table III. Considered by itself, Table IV reveals the presence of several extremely effective fungicides in this series of compounds.

Another illustration of the existence of a selective, "quasi-specific" effect is offered by the graphic presentation in Chart 1 in which a set of data obtained with one representative organism selected from each of the Tables I to IV has been used, viz., *Eberthella typhi*, *Staph. aureus*, *Mycobact. tuberculosis* (hom.), and *Monilia albicans*. This chart also illuminates the difference in the order of magnitude of the bactericidal potencies with respect to the several groups of microorganisms under discussion.

#### POLYALKYL DERIVATIVES

As Table V indicates, this group of compounds (listed in the order of increasing molecular weight) also comprises some highly effective microbicides. The relation between the chemical constitution and germicidal action, while being distinctly in evidence, is not of a sufficiently direct character to permit graphic presentation. Here, too, as in the monoalkyl series, the weight of the substituting groups determines the selective, "quasi-specific" action.

As to the effect upon the germicidal action, of the distribution of the added weight over several substituting radicals, a comparison, e.g., of the substituted parachlorophenol derivatives with a total of four substituting carbon atoms will furnish the necessary illustration. It shows that substitution of parachlorophenol by one alkyl group generally leads to a more effective compound than substitution by two or three alkyl groups with the same total number of carbon atoms; similarly, dialkyl substituted derivatives are considerably more germicidal than trialkyl substituted ones.

It is found in this group, too, that isoalkyl substituted compounds are less effective than the corresponding normal alkyl derivatives. This follows from the comparison of 6-n-propyl-3-methyl-4-chlorophenol and 6-isopropyl-3-methyl-4-chlorophenol (chlorothymol); thus the n-propyl derivative is distinctly more potent than chlorothymol.

Polyalkyl compounds of equal molecular weight, containing isoalkyl groups may show considerable variation in their germicidal action, depending upon their structure.

Whereas in the case of the normal monoalkyl derivatives the maximum effect upon *Eberthella typhi* was shown by a compound with five carbon atoms in the side chain, in the case of the polyalkyl derivatives this maximum is reached by a compound with a total of four substituting carbon atoms. As to the other test organisms in Table V the derivatives with a total of seven carbon atoms generally show the greatest microbicidal efficacy.

#### AROMATIC DERIVATIVES

The aromatic derivatives of parachlorophenol prepared and studied to date comprise the benzyl, and phenylethyl derivatives of parachlorophenol and its methyl homologues listed in Table VI. Because of the greater weight of the aromatic radicals, such substitution might be expected to produce compounds which in their antibacterial behavior would resemble the higher alkyl homologues, i.e., manifest a selective or "quasi-specific" action upon gram-positive and those other organisms which show an analogous behavior in this regard. In keeping with the general idea that particularly the molecular weight determines the point at which the "quasi-specific" germicidal effect becomes apparent, it is found that actually the compounds of this group show a selective action in the above sense, as evidenced by the numerical values of their germicidal potency.

There are among the aromatic derivatives some highly potent germicides. As to the effect of the chemical constitution upon germicidal action, it is noteworthy that the step from the benzyl derivative to the next one with a higher molecular weight is accompanied by different results depending upon the place in the molecular structure to which the additional weight is attached. Thus, 5-methyl-2-benzyl-4-chlorophenol is much less effective than 2-benzyl-4-chlorophenol against the four test organisms of the typhoid-colon group, while 2-phenylethyl-4-chlorophenol is very much more effective than the former. With reference to the other organisms, the difference in the germicidal potencies of the methyl-benzyl and the phenylethyl derivatives is less pronounced.

A further increase in the molecular weight lowers the germicidal action with reference to the bacteria of the typhoid-colon group as shown by the figures obtained with 3, 5-dimethyl-2-benzyl-4-chlorophenol. However, the germicidal potency is increased considerably with regard to the other four organisms. Curiously, 3-methyl-6-phenylethyl-4-chlorophenol, which is isomeric with 3,5-dimethyl-2-benzyl-4-chlorophenol, is not only less effective than the latter, but also, in most instances, weaker than the 2-phenyl-ethyl derivative.

#### BACTERIOSTATIC ACTION

In addition to being potent germicides, certain substituted chlorophenol derivatives manifest considerable inhibitory capacity as well. An investigation of the bacteriostatic effect upon *Staphylococcus aureus* and upon three mycobacteria, viz., smegmatis, tuberculosis (hom.), and leprae (hom.) was carried out with 2-n-amyl-4-chlorophenol and 2-n-heptyl-4-chlorophenol. This experiment was conducted in such a manner as to permit the determination not only of the minimum concentrations required to prevent the growth of the microorganisms, but also that of the status of their viability during the course of their exposure to the inhibitory concentrations. This was accomplished by making transfers from the "inhibitory" media into fresh media after different periods of time.

The results obtained with the two compounds and the four organisms mentioned above are given in Table VII. It is to be noted among other things that whereas in the case of the 2-n-amyl-4-chlorophenol the minimum germicidal concentration is practically four times the minimum inhibitory one, in the case of 2-n-heptyl-4-chlorophenol it is only twice the latter (in the two cases where such comparison can be made).

The effect of  $P_H$  of the medium upon the inhibition by 2-n-amyl-4-chlorophenol and 2-cyclohexyl-4-chlorophenol of the growth of *Staph. aureus* and of *Mycobact. tuberculosis (hom.)* is illustrated in Table VIII. It is found that variations of  $P_H$  in both directions (i.e., to the acid and the alkaline sides) have little effect upon the bacteriostatic capacity of these compounds, a result of distinct practical significance.

#### TOXICITY

It is natural that the discovery of compounds showing such intensive antibacterial properties, should suggest the extension of this study beyond the stage of "in vitro" experiments, and encourage the inquiry into their availability for chemotherapeutic purposes. Some phases of this work are being planned at this time, others are under way.

One important condition of the potential usefulness of a drug for such purposes is a low organotropic against a high parasitotropic action. A preliminary series of experiments aiming at the determination of toxicity of the series of alkyl parachlorophenol derivatives (upon subcutaneous injection in mice\*) shows that this toxicity decreases with increasing molecular weight

\*For the purpose of this test the compounds in question were emulsified in a 0.5 per cent traccanth solution, the proportion of the total quantity of fluid injected to the weight of the animal being approximately the same in all cases.

(Table IX); in other words increasing antibacterial potency (with reference to most of the test organisms) is accompanied by decreasing toxicity. Thus in the case of several of the higher homologues, the enormous dose of 20 mg. per gm. of body weight (corresponding to about 1.5 kg. for an adult human being of 150 pounds) is tolerated. Even though it is inadmissible to draw direct conclusions as to the probable pharmacologic effect upon one species from the observed effect upon another, the preliminary toxicity experiments, too, indicate that the extension of this inquiry into the therapeutic field is not without some promise of success.

#### EXPERIMENTAL PART

*Determination of Bactericidal Action.*—All tests were carried out at 37° C. In all cases 0.5 c.c. of culture was added to 5 c.c. of the various dilutions of the antiseptic substances.

As to the test organisms of the typhoid colon group, cultures of *Eberthella typhi* were procured from the Bacteriological Laboratory of the Food and Drug Administration of the U. S. Department of Agriculture, those of *Eberthella paratyphenteriae*, *Salmonella schottmülleri*, and *Escherichia coli* from the American Type Culture Collection. The method of culturing and preparing these organisms for the tests followed closely that described by Ruehle and Brewer<sup>7</sup> in the case of *Eberthella typhi*, and the testing technic used was the same as given in detail by these authors, i.e., transfers from the medication tubes into fresh media were made after exposures of five, ten, and fifteen minutes, respectively, and the readings were taken after forty-eight hours' incubation. For the sake of space economy the results of the five- and fifteen-minute exposures are left out in Table I (and incidentally also in Tables II to VI), and those of the ten-minute exposures only are given. The "phenol coefficients" were calculated in all cases from the results of the ten-minute exposures to the compounds under discussion on one hand, and to phenol (carbolic acid) on the other. A phenol control test always accompanied the tests with these compounds, carried out on any given day.

As to the three species of pathogenic cocci, the stock culture of *Staphylococcus aureus* was obtained from the Bacteriological Laboratory of the Food and Drug Administration, those of streptococcus and of *Micrococcus catarrhalis* from the Lederle Laboratories. *Staphylococcus aureus* was grown and applied in the test according to the directions given in Ruehle's and Brewer's publication, previously referred to. The same methods were applied in the case of *Micrococcus catarrhalis* yielding results of very satisfactory regularity.

The hemolytic strain of streptococcus used was one of considerable resistance, approaching that of *Staphylococcus aureus*, as evidenced by the results of the phenol-control tests. According to information received from Mr. E. F. Voight, bacteriologist of the Lederle Laboratories, whose assistance is gratefully acknowledged herewith, this strain was isolated originally from a case of scarlet fever and was selected as a scarlet fever type by Dr. A. R. Dochez at Johns Hopkins University. The stock culture for the test was grown on beef infusion peptone broth adjusted to P<sub>H</sub> 7.2-7.4 and was used when twenty-

four hours old. After exposure to the various dilutions of the antiseptics, transfers were made into beef extract peptone broth containing 0.5 per cent of glucose and adjusted to  $P_H$  7.2-7.4.

In the group of the acid-fast bacteria the strains of human and avian tuberculosis and those of human and rat leprosy were procured (with several others, not yet utilized in this investigation) from the U. S. Marine Hospital in Carville, Louisiana, through the courtesy of Dr. O. E. Denney to whom the authors wish to express their gratitude at this opportunity. The four original culture tubes received, were described as follows:

- M. tuberculosis hominis* Koch
- M. tuberculosis avium* Arlong (Phipps)
- M. leprae human* Clegg 1, Duval No. 105
- M. leprae murium*, Nat. Inst. Health

These four cultures were chosen because of the rapid growth which could be detected easily twenty-four hours after seeding. The medium for both stock cultures and subcultures was beef extract peptone broth containing 5 per cent of glycerin and adjusted to  $P_H$  7.4. The stock cultures were grown for from five to seven days in strong bottles containing glass beads. Shortly before the test the bottles were stoppered with sterile rubber stoppers and shaken until a homogeneous suspension was obtained. This suspension was then poured through a sterile 200 mesh monel metal sieve in order to eliminate the larger particles. Final readings were made after incubation for seven days.

The original strain of *Mycobacterium smegmatis* was obtained from the American Type Culture Collection. It was grown and applied in the same manner as *Staphylococcus aureus* except that the stock emulsion for the test was forty-eight hours old and that final readings of the subcultures were made after one week's incubation.

As to the group of pathogenic fungi, the cultures of *Achorion schönleini* and of *Monilia albicans* were procured from the American Type Culture Collection. The authors are very grateful to Dr. E. D. Osborne of Buffalo, N. Y., for two cultures of trichophyton, one of which was used in this work.

*Achorion schönleini* and *Trichophyton rosaceum* were treated in the same manner. Both were grown on Sabouraud's agar which was also used for subcultures. The stock suspension for the test was prepared in the following manner: The growth of from ten to fifteen days was removed from the slant by means of a hooked platinum wire and placed in a sterile bottle with a layer of glass beads at the bottom. Four cubic centimeters of sterile normal saline was added, the bottle stoppered with a sterile rubber stopper and shaken vigorously, until the mass was broken up completely. Then another 6 c.c. of saline was added and the bottle shaken again. The suspension thus obtained was poured into a glass tube and the latter centrifuged for one minute at the lowest speed, in order to allow the large unbroken particles to settle to the bottom. The supernatant suspension was removed with a sterile pipette and diluted with double the amount of saline. As a rule the yield

from each culture tube was about 15 c.c. of suspension ready for use. The subcultures were held at 28° C. for ten days before the final readings were made.

*Monilia albicans* was also grown and subcultured on Sabouraud's agar. The suspension in normal saline was obtained by washing off a three- to five-day-old growth from the surface of the slant. Each tube gave 10 c.c. of the suspension for the test. Readings were made after incubation at 28° C. for five days.

#### DETERMINATION OF BACTERIOSTATIC ACTION

Regular bacteriostatic tests were carried out in the customary fashion by inoculation of media containing different concentrations of the antiseptic substances, and observation of the incubated tubes.

Where it was desired to determine the status of viability of the microorganisms in the presence of bacteriostatic concentrations, in relation to the time of exposure, the following procedure was used: To 9 c.c. of broth (of the same composition as used in the bactericidal tests) 1 c.c. of the antiseptic solution was added, containing ten times the concentration which appears in Tables VIII and IX. A spiral loop (of five turns of 2.18 mm. inside diameter, wire gage 23B and S., and holding approximately 0.02 c.c.) was used to plant the culture in this mixture previously warmed to 37° C. The tubes were kept

| sec. Amyl                     | 15.0                  |
| n-Hexyl                       | >20.0                 |
| Cyclohexyl                    | >20.0                 |
| n-Heptyl                      | >20.0                 |

in the incubator for the stated periods of time and transfers were made into fresh media after fifteen minutes, one, two, four, six, twenty-four, forty-eight, and seventy-two hours with a loop of the same size. Final readings of the subcultures were made after incubation for forty-eight hours in the case of *Staphylococcus aureus*, and after one week in that of the acid-fast bacteria.

It is of possible practical interest that according to the outcome of several tests, both stock solutions and emulsions of the compounds under discussion, and also the final dilutions in the medication tubes may be sterilized in the autoclave without suffering any impairment of their bactericidal potency.

#### SUMMARY

The bactericidal and fungicidal action of the homologous series of parachlorophenol derivatives has been investigated with the aid of the following microorganisms: *Eberthella typhi*, *Escherichia coli*, *Eberthella paradysenteriae* (Flexner), *Salmonella schottmülleri*, *Staphylococcus aureus*, streptococcus (hemol. strain), *Micrococcus cutarrhalis*, *Mycobacterium tuberculosis* (hom.) and (avium), *Mycobacterium leprae* (hom.) and (mur.), *M. smegmatis*, *Monilia albicans*, *Trichophyton rosaceum* and *Achorion schönleini*.

In confirmation of previous preliminary findings (stated in the initial paragraphs of this paper), the presence in this series of some derivatives of an extraordinarily high bactericidal and fungicidal potency has been established. The relationship between the chemical constitution and antibacterial action has been discussed in some detail. A "quasi-specific" effect of certain higher alkyl homologues upon the test organisms, exclusive of the bacteria of the typhoid-colon group, appears to divide the microorganisms in two groups, the division agreeing partly, but not entirely with that obtained by means of the Gram stain, and evidently also with that based upon their susceptibility to the inhibitory action of certain basic dyes. Nevertheless, the class of compounds under consideration comprises some bactericides, highly effective against the organisms of the typhoid colon group as well.

In addition to the monoalkyl derivatives, several polyalkyl and aromatic compounds were studied and the regularities in their antibacterial behavior were pointed out.

The bacteriostatic potency of some of the derivatives was also investigated and found to exist to a remarkable degree not only with respect to staphylococcus, but also with respect to several acid-fast strains. The comparative independence of the bacteriostatic capacity from the  $P_H$  within rather wide limits was emphasized as being of possible practical significance.

This great antibacterial efficacy of certain derivatives of the homologous parachlorophenol series was found to be accompanied by very low toxicity to mice. Specifically, the increase in weight of the substituting alkyl radical which causes, within certain limits, an increase in the germicidal potency, produces also a sharp decline in the toxicity to animals. This combination of high antibacterial capacity and low toxicity to animals, as encountered in several instances, suggests the extension of the present inquiry into the field of chemotherapy.

Our thanks are due to Mr. A. Grawehr of our laboratory staff, for valuable assistance rendered in the bacteriologic phase of this work.

## NORMAL ERYTHROCYTE, HEMOGLOBIN AND PACKED CELL VOLUME STANDARDS IN YOUNG MEN\*

### A STUDY OF 100 SUBJECTS

ORVILLE S. WALTERS, A.M., LAWRENCE, KAN.

THE unsatisfactory character of the data on which the long-accepted normal erythrocyte and hemoglobin values are based has been pointed out frequently in recent years. The increasing use of the blood indices or of the average volume and hemoglobin content of the individual erythrocyte in differentiating anemias has emphasized the need of dependable normal values. In an effort to provide adequate data for reliable standards, a number of extensive studies have been made on young men. Haden<sup>10</sup> in 1922 published a study which included observations on 20 men between the ages of eighteen and thirty. This series was later increased to 35.<sup>14</sup> Osgood<sup>21</sup> in 1926 followed with data on the blood of 137 men between nineteen and thirty. Wintrobe and Miller<sup>33</sup> made similar observations on 100 men between the ages of twenty and thirty. Foster and Johnson<sup>7</sup> followed with a similar study of 115 normal men. Even with these data, general erythrocyte and hemoglobin standards are by no means established,<sup>1, 5</sup> and the need for additional study in other localities has often been pointed out.<sup>12, 24, 26</sup>

The present study is based upon the observations made on 100 men between the ages of twenty and thirty. The subjects were medical and college students, all of whom had been found in good health by thorough physical examination. Since previous investigation has shown that both muscular activity<sup>17</sup> and rest<sup>22</sup> produce significant fluctuations in the erythrocyte count, the samples of blood were drawn as soon as the subjects presented themselves at the laboratory.

\*From the Department of Physiology, University of Kansas.  
Received for publication, June 23, 1932.

No other effort was made to control physical activity. The data are, therefore, believed to be comparable to previous studies in which the subjects have, also, apparently been chosen at random with respect to physical activity. Most of the observations were made during the month of September.

#### METHODS

A 6 c.c. quantity of blood was drawn from an arm vein, 5 c.c. being placed in a 15 c.c. graduated centrifuge tube containing 1 c.c. of 1.6 per cent sodium oxalate solution. The 1 c.c. of blood was placed in a second tube containing a small amount of dry oxalate and was later used for making counts and hemoglobin determinations. All tubes were tightly stoppered immediately, and samples were centrifuged or diluted before any known changes which would affect any of the observations could occur in the blood. Precautions were taken to prevent stasis in arm veins when withdrawing blood.

Cell volume was ascertained by centrifuging the tubes containing the 5 c.c. of blood in 1.6 per cent oxalate for one hour, which is considered adequate by Haden,<sup>13</sup> at a speed of 2,800 r.p.m. in a centrifuge with a working radius of 13.5 cm. The tubes were allowed to return to room temperature before readings were made. The percentage of cells was calculated from the readings of the graduated scale on the tube.

Erythrocyte counts were made after dilution in Trenner pipettes, in Levy-Hausser chambers having improved Neubauer ruling, all of which apparatus had been tested by the U. S. Bureau of Standards. The pipettes were agitated for three minutes in a mechanical shaker which was carefully checked to eliminate the possibility of any mechanical hemolysis. At least two dilutions with Hayem's solution were made from each sample and, if necessary, additional dilutions were made until counts from separate pipettes were obtained which agreed within 100,000 cells. Blood was thoroughly mixed by repeated inversion of tubes before samples were taken out, and diluted samples were allowed to settle completely in the chamber before counting. Trenner pipettes were checked with U. S. Standard Thoma pipettes and were found to give concordant readings.

Hemoglobin was estimated by the Newcomer method. Determinations were made after the acid hematin solution had stood for one hour. All readings were made by daylight. Each reading recorded is the average of six observations of the colorimeter. In order to verify the dependability of the

| 7                      | 15.15              | 15.30                  | -0.15                    |
| 8                      | 16.12              | 15.79                  | +0.33                    |
| 9                      | 15.20              | 15.85                  | -0.65                    |
| 10                     | 25.78              | 25.81                  | -0.03                    |

Newcomer disc, the apparatus was checked against the Van Slyke oxygen capacity method on 10 different samples of blood. The results were as shown in Table I.

Because of the close correspondence of this series of comparative determinations, no corrections were applied to the Newcomer readings. All cell counts and hemoglobin determinations were made by the same individual.

#### THE ERYTHROCYTE COUNT

Other investigators<sup>24, 33</sup> have reviewed the literature dealing with normal erythrocyte values and have shown how prevailing standards originated from a surprisingly small number of observations. In the United States, four important studies of normal men in the age range from eighteen to thirty, and using accurate methods for erythrocyte count, total hemoglobin and total cell volume have appeared recently.

Working in Kansas, Haden observed in a series of 20 men, aged eighteen to thirty, a mean erythrocyte count of 5.08. The lowest count recorded was

Fig. 1.—Frequency distribution of erythrocyte count in 100 young men. The median, 4.86, is indicated by a broken line and the mean, 4.84, by a solid line.

4.52 and the highest, 5.62. When the series was increased to 35 subjects, the mean count was 5.05 million. Osgood, in Oregon, found the mean erythrocyte count for the 137 men of his series to be 5.39 million, ranging from 4.4 to 6.4 million, with 90 per cent lying between 4.7 and 6.1 million. Wintrobe and Miller, working in Louisiana, observed a mean of 5.85 million in the 100 men examined by them, with 95 per cent between 5 and 6.90 million. The minimum and maximum values of this group were 4.68 and 7.53, respectively.

Emerson<sup>7</sup> in Baltimore reported the average count of 176 men between the ages of twenty and twenty-five as 5 million, with only 8 per cent below 5 million and 8.5 per cent above 6 million. Haden<sup>15</sup> has recently reported a series of counts made by medical students in Kansas City on their own blood, in which a mean of 4.997 was found, the average of 54 students in 1929 to 1930 being 4.85 million. Figures reported by various other investigators are given in Table II.

In the 100 men observed in the present study, the mean erythrocyte count was 4.84 million per cubic millimeter of blood, the counts ranging from 4.10 to 5.55 million. Of this number, 90 per cent lay between 4.31 and 5.35 million,

## TOTAL HEMOGLOBIN AND COLOR INDEX

Haden, using the Van Slyke method, found in his study of 35 men a mean total hemoglobin of 15.63 gm. per 100 c.c. of blood. Osgood, employing the Osgood-Haskins method of hemoglobin determination, standardized by the Van Slyke, found a mean of 15.76 gm. in his series of 137 men. Ninety per cent of the values were between 14 and 18 gm. Wintrobe and Miller,<sup>22, 24</sup> using the Newcomer hemoglobinometer corrected by the Van Slyke method, obtained a mean hemoglobin figure of 17 for 100 male subjects, with 73 per cent of the determinations ranging between 15.5 and 18.5 gm. Foster and Johnson found a mean value of 15.63 gm. per 100 c.c. for 115 men.

Several large series of normal men have been investigated by workers in other localities. The mean values found by Harrop,<sup>16</sup> Orias,<sup>21, 22</sup> Parodi,<sup>26</sup> Sokhey,<sup>30</sup> Parjono et al.,<sup>25</sup> Tenconi,<sup>31</sup> Price-Jones,<sup>28</sup> Dill,<sup>4</sup> and more recently, by Jenkins and Don,<sup>19</sup> are shown in Table III.

The familiar work of Williamson is criticized<sup>27</sup> because a standard of recrystallized hemoglobin was used. Horneffer's<sup>18</sup> mean of 16.03 gm. per 100 c.c. for 40 men has been questioned<sup>28</sup> for the same cause.

Fig. 2.—Frequency distribution of hemoglobin values in 100 young men. The median, 15.02, is indicated by a broken line and the mean, 15.12, by a solid line.

Various methods of determination have been reported. Sackett,<sup>29</sup> using the Wong iron method, found a mean value of 16.71 gm. per 100 c.c. in 15 normal men. Chia Yu Tien<sup>31a</sup> reports a series of observations on 321 healthy Chinese in which a mean of 97.4 per cent by the Sahli method was found. Komocki<sup>20</sup> records a mean of 86 per cent Sahli in 17 healthy men associated with an average red count of 5.97 million. Cabigting,<sup>2</sup> using the Bausch and Lomb hemoglobinometer, found a mean of 82.7 per cent for 22 normal male Filipinos.

The mean value found for the 100 subjects of the present study was 15.12 gm. per 100 c.c. of blood, 90 per cent of the figures lying between 13.25 and 17.03 gm. The extremes were 12.89 and 18.70 gm.

In the calculation of color index, it is of course necessary to employ an arbitrary standard for erythrocytes and hemoglobin which shall be regarded as 100 per cent. The use of 5 million is universally accepted as 100 per cent

of red cells. Osgood, on the basis of his own observations and the data of previous investigators, recommended the use of the hemoglobin coefficient, 14.7 gm., to represent 100 per cent. Wintrobe adopted 14.6 gm. as a more accurate figure to represent 100 per cent.

The inadaptability of a hemoglobin coefficient derived largely from one or two series to all localities is demonstrated by employing the figure used as 100 per cent by Wintrobe in four of the separate series being compared. The data of Osgood and of Wintrobe and Miller, when so treated, show a mean color index of 1. Haden's subjects show a mean color index of 1.07 and those of the present series, 1.08, with Wintrobe's 100 per cent figure. If, however, a hemoglobin coefficient is calculated from the combined data of Haden and of this study, the resulting figure, 15.59 gm., when used as 100 per cent hemoglobin, gives a mean color index of 1.006 for the subjects of the present series, 85 per cent of which are between 0.85 and 1.15.

#### TOTAL VOLUME OF PACKED CELLS AND VOLUME INDEX

Since the procedure followed by Osgood and by Wintrobe and Miller employed powdered oxalate as an anticoagulant, corrections were applied to

Fig. 3.—Frequency distribution of total volume of packed cells in 100 young men. The median, 46.8, is indicated by a broken line and the mean, 46.5, by a solid line.

their original figures. Osgood, using 20 mg. powdered oxalate to 10 c.c. of blood, obtained an average total volume of 44.84 c.c. of packed cells per 100 c.c. of blood in the 94 subjects who were so examined. This figure was increased by 3.5 per cent to correct for shrinkage of the cells, giving a revised figure of 46.4 c.c. packed cells per 100 c.c. of blood. Ninety per cent of the values ranged between 40 and 50 c.c.

The corrected mean of Wintrobe and Miller is 46.5 c.c. of packed cells per 100 c.c. of blood. This was obtained by adjusting for the 6.7 per cent shrinkage in volume with the 40 mg. of oxalate per 10 c.c. of blood used by them. Of the corrected values, 85 per cent ranged between 40 and 50 c.c.

The mean total cell volume found in the present series was 46.5 c.c. packed cells per 100 c.c. of blood, with 92 per cent of the total volume determinations between 43 and 50 c.c. This average agrees with Haden's first published data<sup>10</sup> in which 1.6 per cent oxalate solution was used as an anticoagulant.

Haden<sup>13</sup> has since demonstrated that 1.4 per cent oxalate is more nearly isotonic with human blood than 1.6 per cent although the difference is small. The mean value found by Foster and Johnson for 40 subjects using heparin as an anticoagulant is slightly greater, as might be expected. Peters and Van Slyke<sup>27</sup> mention the unpublished packed cell volume determinations of Eisenman as agreeing excellently with those of Haden and Osgood. Pearl and Miner<sup>26a</sup> report a mean of 45.59 c.c. in their study of 272 normal men.

In spite of the fact that the various average figures for total volume of packed cells agree so closely, the great divergence in red cell counts produces volume coefficients in each instance which are widely separated. Osgood's corrected volume coefficient is 43.04 c.c., while the high average cell count found in Wintrobe and Miller's subjects gives a volume coefficient of 39.94. Foster and Johnson calculated 41.4 as the volume coefficient of their 40 subjects. Osgood, as well as Wintrobe and Miller, employed 41 c.c. as 100 per cent in their calculations, giving volume indices of 1.00 and 0.97 respectively. The use of 41.0 c.c. as 100 per cent would give a volume index in Haden's group of 1.12 and in this series, of 1.18. Obviously, again, the standard chosen as 100 per cent must, judging from the above calculations, be a local one, at least for the present. If the data of Haden and of this series are combined, a volume coefficient of 47.4 c.c. is derived, which, when considered as 100 per cent total cell volume, gives a mean volume index in this series of 1.017 with 90 per cent between 0.89 and 1.15.

#### SATURATION INDEX

Employing the standards used by Wintrobe, a hemoglobin coefficient of 14.6 gm. and a volume coefficient of 41 c.c., the 100 subjects of Wintrobe and Miller average 1.02, the Oregon men, 0.98, and Haden's Kansas City group 0.96 in saturation index. The series under consideration would average 0.92. If, however, 15.59 gm. hemoglobin and 47.4 c.c. packed cells are taken as 100 per cent standards, the mean saturation index obtained is 0.99 in this series, with 90 per cent ranging between 0.85 and 1.12.

#### MEAN CORPUSCULAR VOLUME, HEMOGLOBIN AND HEMOGLOBIN CONCENTRATION

The method of calculating mean corpuscular volume, hemoglobin and hemoglobin concentration has been explained frequently elsewhere<sup>10, 11, 35, 36</sup> and is therefore omitted here. Mean corpuscular volume refers to the average volume of individual erythrocytes, stated in cubic micra. Mean corpuscular hemoglobin expresses the average amount of hemoglobin in micromicrograms (grams  $\times 10^{-12}$ ) present in the erythrocytes. Mean corpuscular hemoglobin concentration expresses the amount of hemoglobin in proportion to the volume of the erythrocyte and is stated in percentage.

The mean corpuscular volume obtained in this study, 96.5 cubic micra, is higher than that found in any of the other series compared in Table IV. The normal range for the age group, sex, and locality of this study is found between 82 and 107 cubic micra, since 90 per cent of the observations occurred within those limits.

These figures tend to confirm the relationship suggested by the work of Emmons<sup>6</sup> on various mammalian as well as human bloods, that the volume of the individual erythrocyte appears to vary inversely with the total number found, a larger corpuscular volume tending to compensate for the smaller number of cells.

Haden's average for mean corpuscular volume in men is 92 cubic micra. Wintrobe found 79.8 cubic micra for an average, while the mean figure calculated from Osgood's data is 86.1 cubic micra. Foster and Johnson's figure is 85.9.

Fig. 4.—Frequency distribution of mean corpuscular volume in 100 young men. The median, 96.3, is indicated by a broken line and the mean, 96.5, by a solid line.

Fig. 5.

Fig. 5.—Frequency distribution of mean corpuscular hemoglobin in 100 young men. The median and the mean are identical, 31.4.

Fig. 6.

Fig. 6.—Frequency distribution of mean corpuscular hemoglobin concentration in 100 young men. The median, 32.6, is indicated by a broken line and the mean, 32.4, by a solid line.

Since the calculation of corpuscular volume, hemoglobin and hemoglobin concentration is simple and does not involve any arbitrary standard, these constants have been recommended frequently in preference to the volume, color, and saturation indices for clinical work. However, it is clear that even for the application of these terms to specific cases, well-established normals for the given conditions, age group, and sex should be known. For example, although Wintrobe<sup>36</sup> states that "values above 95 cubic micra or below 75 cubic micra are probably a manifestation of abnormality," more than half of the

normal subjects observed in the present investigation showed a corpuscular volume greater than 95 cubic micra.

The average figure for mean corpuscular hemoglobin found in the subjects of this study was 31.4 micromicrograms, with 92 per cent lying between 25 and 37 micromicrograms. This mean is almost identical with Haden's average of 31.0 micromicrograms for 35 men between eighteen and thirty, and agrees closely with the average figure found by Foster and Johnson, 30.03 micromicrograms. The same mean was observed both by Osgood and by Wintrobe and Miller, 29.2 micromicrograms.

The average found for corpuscular hemoglobin concentration was 32.4 per cent. Ninety-one per cent of the calculations lay between 27.5 and 36.5 per cent. Haden's average of 33.7 per cent and Osgood's, 33.9 per cent, are in close agreement with this figure. Wintrobe found an average of 36.6 per cent, while Foster and Johnson recorded a mean of 34.77. Horneffer calcu-

lated a mean corpuscular hemoglobin of 32.4 for his series of 40 healthy men. The criticism of his method of hemoglobin determination has already been mentioned.

#### THE QUESTION OF GEOGRAPHIC VARIATIONS

The comparatively wide differences which have been found to exist in hemoglobin and erythrocyte count have frequently raised the question of possible geographic variations other than the well-recognized increase with altitude.

Parjono, Radsma and Joenoes<sup>25</sup> compiled data on blood iron and oxygen capacity in an effort to find some correlation between the amount of hemoglobin and geographic latitude. The data used were found insufficient to establish any clear relationship.

In Tables II and III are listed erythrocyte and hemoglobin determinations from various geographic localities. From these figures it is apparent that any correlation on the basis of geographic locality is very difficult, since in several cases, investigators working in the same locality have secured widely differing results. There are, however, few striking differences.

Many other factors than geographic location are doubtless existent as, for example, in the case of the difference found between poorer natives and the better-situated students and native doctors in the Java group of Parjono, et al. For this particular difference these authors suggest the prevalence of intestinal worms among the poorer classes as a possible explanation.

Orias<sup>22</sup> found a definite difference between common soldiers, officers and students in Buenos Aires (Table III). He concludes that social condition is an important factor in hemoglobin level. Horneffer also noted this difference, finding 16.25 gm. as the mean value for 20 students and 15.80 gm. as the mean for 20 soldiers.

Price-Jones suggests chronic carbon monoxide poisoning from motor cars, with an accompanying compensatory increase in hemoglobin and red blood cells to account for the difference in hemoglobin content which was found by him in London and Boston. This explanation is claimed by Jenkins and Don to have been invalidated by observations made on mechanics. These investigators find an even higher mean hemoglobin value for individuals from various localities in England than Price-Jones found in Americans.

The possibility of a difference in hemoglobin level between smokers and nonsmokers due to carbon monoxide has also been investigated,<sup>32a</sup> but no significant difference was found.

Some significant differences due to technic would seem inevitable in any list of investigations as large as those quoted in Tables II and III. Further sampling of the normal population on an extensive scale is needed to clarify the question of normal standards for general use.

#### SUMMARY

1. Careful observations made on 100 healthy men between the ages of twenty and thirty in Kansas show a mean erythrocyte count of 4.84 million, 15.12 gm. of hemoglobin per 100 c.c. of blood and 46.5 c.c. of packed cells per 100 c.c. of blood.

2. When a hemoglobin coefficient of 15.59 gm. and a volume coefficient of 47.4 c.c. are employed as 100 per cent standards, the color, volume and saturation indices are approximately 1.

3. Calculations from the above data give the following average figures: for mean corpuscular volume, 96.5 cubic micra; for mean corpuscular hemoglobin, 31.4 micromicrograms; for mean corpuscular hemoglobin concentration, 32.4 per cent.

4. Comparison of erythrocyte and hemoglobin values found by investigators in widely separated areas shows no apparent relation to geographic location. Technical variations may be one of the important factors in observed differences.

The author is indebted to Dr. Ralph I. Canuteson, Student Health Director at the University of Kansas, for kindly providing laboratory facilities in Watkins Memorial Hospital.

## WUCHERERIA (FILARIA) BANCROFTI INFECTION IN MAN WITH AN UNUSUAL HISTORY\*

---

### CASE REPORT

---

HILDRUS A. POINDEXTER, M.D., PH.D., AND R. FRANK JONES, M.D.  
WASHINGTON, D. C.

---

THE occurrence of Wuchereria infection in a person who has remained within the vicinity of the District of Columbia all of his life is so unusual that we feel justified in reporting it.

We have not been able to discover all the links in the chain of circumstances leading to the infection. This, together with the usually accepted epidemiology of filariasis, while incidentally serving to remind the general practitioner of its possible occurrence in this part of the country, also serves to focus more interest of the entomologist on the way or ways in which the patient may have become infected. From an epidemiologic standpoint we thought of four possibilities: (1) a wider general distribution of species of mosquitoes generally known to serve as vector for this disease; (2) a special means of distribution by these same mosquitoes laying their eggs in the few centimeters of water frequently found in the bottom of the lifeboats on freighters coming from endemic ports with a crew, some of which may be carriers; the larvae from these eggs become mosquitoes in time to bite the crew and they, after the usual incubation period, infect persons in any subsequent port; (3) the common mosquito of this vicinity, which may assume the rôle of vector when in contact with carriers from an endemic area; (4)

---

\*From the Department of Bacteriology, Preventive Medicine and Public Health and the Department of Surgery—Urological Section; Howard University School of Medicine and Freedman's Hospital.

and lastly, some species of tick, which may serve as vectors. The last possibility is of interest chiefly because *Filaria perstans*, an organism very much like *Wuchereria bancrofti*, except that it does not have a sheath, is transmitted by a certain species of tick, and recently we have had an increase in tick (Eastern type of Rocky Mountain spotted) fever in this vicinity.

#### CASE REPORT

X. Y., a negro janitor, aged twenty-nine years, was admitted to Freedman's Hospital, May 15, 1933, with a chief complaint of progressive enlargement of the scrotum and right leg and foot with several areas of suppuration from the scrotal sac, one on the right buttock, and glandular enlargement and ulceration of the left axillary region.

The past history is important in that the patient has lived in Washington all of his life and has never travelled more than one hundred miles from Washington, and when he did leave the city, it was only for a short time, generally on fishing trips.

He has had measles, mumps, whooping cough, and eczema during childhood, but has otherwise enjoyed good health up to the beginning of the present illness. His appetite has remained good. He has used alcohol and tobacco in moderation, but no narcotics.

The only contacts which he can recall with the tropics or subtropical zones are: prior to the present illness he had worked as janitor for a family of Filipinos, then living in Washington; and his family at various times received packages, some of which contained plants, from relatives in Mississippi. The family history is essentially negative except for an almost complete progressive blindness in his father (cataract).

*Present Illness.*—About five years ago the patient, without any previous chill, fever or other symptoms of illness, began to have slight pains in the umbilical region. This continued for some time. Shortly after this he observed that his scrotum was enlarging. This continued, and about two weeks after the enlargement was noticed, two small areas of ulceration were observed where the scrotal walls rubbed against the thighs.

At this time his wife left him, accusing him of having some type of venereal disease.

He was treated by a private physician for about one year with various local and internal medications, but when the scrotum continued to enlarge, he was hospitalized for ten weeks at Gallinger Municipal Hospital. There, various studies and treatments were performed without any check of the progressive enlargement of the scrotum. They did not find microfilariae in the blood. His general condition of health was good up to the time of admission to Gallinger Hospital.

After leaving the hospital, he did not return to work because the size of the scrotum and the several areas of ulceration made walking more difficult.

For the last four years he has not worked nor received any systematic medical treatment. During this time the scrotum has continued to enlarge. Areas of suppuration have developed over the scrotum and areas of excoriation over the inner surface of the thighs where they rub against the scrotal wall. Glandular enlargement developed in the axillae with subsequent suppuration of the left axilla. About this time a small ulceration developed over the right buttock and about two years ago the right leg and foot began to enlarge and to become progressively rough.

In the light of the above progress he was advised by a member of the staff of Freedman's Hospital to come into the hospital for study. This he decided to do and was admitted May 15, 1933.

*Physical Examination.*—The general examination revealed a very obese negro male weighing more than 350 pounds, without any evidence of marked discomfort or illness, who was in a jovial mood. The head and neck were normal. The chest and upper extremities, except for some glandular enlargement in each axilla and slight suppuration of the left axilla, were normal. The abdomen showed abundant adipose tissue.

Genital examination revealed a very greatly enlarged scrotum, appearing to weigh about 25 pounds. It was deeply pigmented here and there, nodular and hard in places. Other

areas reflected light due to the drying of serum which had oozed from its surface, while still others presented deep sinuses covered by a purulent exudate. Where the folds of pendulous abdominal fat met the fat on the anterior surface of the thigh on either side, the valleys of the inguinal regions presented ulcerated surfaces penetrated by tunneled sinuses. These showed a marked tendency to granulation. While the penis was completely invaginated within the overgrowth of scrotal tissue, there seemed to be a marked proliferation of prepubic tissue, which was unusually pendulous. There were areas of excoriation over the inner surface of each thigh, where the very much enlarged scrotum rubbed against them. The right buttock showed a small area of suppuration. The left leg and foot, except for the marked dryness and scales, were apparently normal. The right leg was larger around by two inches at the calf and knee than the normal leg. The right leg and foot showed scaling and pigmen-

Fig. 1.—A, Before treatment. Measurements: Left, thigh 32 inches; knee 22 inches; calf 20 $\frac{1}{4}$  inches; ankle 14 $\frac{1}{2}$  inches. Right, thigh 32 $\frac{1}{4}$  inches; knee 24 inches; calf 22 inches; ankle 14 inches. B, After treatment.

tion together with a few shining areas in which serum appeared to be oozing. There was no definite ulceration of either limb.

A clinical diagnosis of elephantiasis was made by the staff.

*Laboratory Examination.*—Several thick smears of blood taken during the night, one at 9:15 P.M. and another at 10:30 P.M. on separate nights, showed microfilaria when stained by the Giemsa method. The coagulation time was five minutes. Red blood corpuscles 4,670,000; white blood cells 14,000. Differential: Small lymphocytes 36 per cent, large lymphocytes 25 per cent, large mononuclears 8 per cent, transitionals 6 per cent, polymorphonuclear neutrophils 20 per cent, eosinophils 5 per cent. Blood Wassermann was negative. Urine showed no microfilariae, a few epithelial cells, and a positive indican test; otherwise nothing significant.

Stools were free from parasites, ova or larvae. Bacteriologic culture from several of the areas of ulceration and from some of the deep tissue removed at operation showed various micrococci, *Staphylococcus albus*, a nonhemolytic streptococcus, which fermented mannite and was considered to be *Streptococcus fecalis*; from one area there was a diphtheroid organism. The condition of the patient while in the hospital was uneventful. The earlier treatment consisted primarily of Sitz bath and mild local antiseptics in an attempt to clear up most of the secondary infection.

Attempts were made on two occasions to drain fluid from the enlarged serotum. Several punctures with various sized needles failed to locate any definite pockets of fluid. We interpreted the enlarged serotum to be due to chronic edema, and proliferation of the subcutaneous connective tissue secondary to this edema, the pathologic basis for which is the blocking of the lymph circulation.

The patient was sufficiently clear of secondary infection by June 2, 1933, to warrant an operation. On June 2, 1933, under general ether anesthesia, the enlarged serotum was removed together with some of the inguinal lymphatics. Also an extensive section of the prepubic redundancy was removed, effecting complete recovery of the penis. It was found that the skin which covered the penis was not thickened, but only evaginated, due to the weight of the involved serotum. The testicles were found to be normal in every respect. They were stripped

Fig. 2.—A. Shows a low-power magnification of the *Microfilaria* stained with hematoxylin as described above. B. Shows the same *Microfilaria* under a higher magnification.  
The Technic of Preparation Was as Follows.—Slides were made from the centrifuged specimens of citrated blood, which had also been dehemoglobinized by distilled water. The residue was used for the smear. The smear was fixed in a solution containing equal parts of alcohol and ether for five minutes; stained with warm hematoxylin for eight minutes, decolorized for two seconds in 80 per cent alcohol to which had been added a few drops of hydrochloric acid and dried for examination.

of all of the proliferative tissue and covered in a new sac by joining the healthy skin of the perineum and inner side of the thigh to the normal skin covering the penis. For several weeks the penis was visible. Erection was noted on many occasions. Failure to remove sufficient subcutaneous tissue in the prepubic region encouraged the return of redundancy with resulting invagination of the penis. The patient had an uneventful convalescence from the operation. He was discharged from the hospital July 7, 1933, markedly improved, with instructions to return at intervals to the out-patient department for observation and further treatment.

#### DISCUSSION

In view of the nodular swellings under the arms and elsewhere, we were compelled to consider a probable onchocerciasis, a rare disease due to *Onchocerca volvulus*, a member of filariidae family, and transmitted by some gnat of the Simuliidae family.

The geographic distribution of the onchocerciasis, as well as the history of this case, made that solution highly improbable from the beginning, and the microscopic study of the microfilaria definitely ruled it out.

Clinically the case was one of elephantiasis. We therefore had to consider the etiology from three standpoints: infection with *Wuchereria bancrofti* and a secondary invader which some believe to be primarily responsible for the ulceration and much of the lymphatic blockage or elephantiasis of a nonparasitic type resembling the cases reported by Gager,<sup>1</sup> and others. While the works of O'Connor and Hulse,<sup>2</sup> and O'Connor<sup>3</sup> seem to show that elephantiasis in *Wuchereria* infection may occur without secondary infection, we believe that this case is one in which the secondary infection by the streptococci and staphylococci is an important secondary etiologic factor in producing the syndrome.

The question of where and by what means the patient received the infection seems to be the most important consideration here.

*Wuchereria bancrofti* infection, while common in various areas throughout the tropics and subtropical belts, is most important as a United States menace because of its prevalence in the Islands and ports of the Caribbeans and its endemicity in Charleston, South Carolina. Man is the only proved intermediate host harboring the adult worms and the sexual phases, and the mosquito is the only proved definitive host in which complete development may take place, and is thus the vector of interest.

Since we have evidence that man cannot infect man directly, but that the microfilariae must undergo a certain period and complete certain stages of development in the mosquito before the infective form is produced and is thus ready to be transmitted to another person, the vector becomes the important problem here. There are at least four known genera of the order Diptera in which the complete development of the *Wuchereria bancrofti* is known to be possible: viz., *Aedes*, *Anopheles*, *Culex*, and *Mansonia*. There are several species under each of these genera in which the complete development of *Wuchereria* is known to be possible, but for all practical purposes in the United States only three species are important as vectors. They are *Culex fatigans*, common in the West Indies and South Carolina; *Anopheles (Nyssorhynchus) albimanus*, common in the Caribbean; and *Aedes variegatus*, common in the Pacific Islands. While such species as *Anopheles costalis* are very efficient vectors, a geographic consideration of its habitat, primarily confined to the West Coast of Africa, the small amount of travel and trade between those ports and North America and the long distance make it a vector of almost negligible consideration in this case. For many of the same reasons, *Aedes variegatus* becomes less likely as a vector in this case. Using the above methods of reasoning, we feel that the frequent contact between Baltimore and the Caribbean and Charleston, South Carolina, makes the *Culex fatigans* or *Anopheles albimanus* the most likely vector in this case.

The question of this man as a carrier and a menace is worthy of mention only to rule out the danger. As pointed out by Manson-Bahr,<sup>4</sup> when fewer than one microfilaria were present in 2 c.c. of the patient's blood, the appro-

priate mosquito frequently failed to acquire infection. In this case, there was about one microfilaria per 3 c.c. of blood as averaged by our concentration method before operation and about one microfilaria per 5 c.c. of blood now. The usually accepted vectors are infrequent in this locality. We also know that some of the microfilariae are destroyed during their stay in the mosquito.

These facts together with the fact that both a male and a female must become lodged in the same area in man and then grow and develop their reproductive organs preparatory to bringing about a fecundated adult female parent before multiplication can take place, make this case insignificant as a danger. However, if the patient were more heavily infected, he would be a potentially dangerous carrier.

There is no accepted medication. Many clinics in the tropics report the trial and failure of various intravenous medications. I was impressed with the reports of success still claimed by the staff of the Municipal Hospital of Fredericksted, St. Croix, Virgin Islands, while visiting there during the summer of 1932. The other hospitals in various parts of the Caribbean did not report such results. While the surgical treatment selected in this case is primarily palliative and of no unusual significance, untold individual aid has been rendered this patient.

#### SUMMARY AND CONCLUSION

*Wuchereria bancrofti* infection may occur in persons living in the temperate zones who have not had any obvious contact with the commonly accepted vector. Such a case is here reported.

We wish to express our appreciation to Doctors William H. Taliaferro and Clay G. Huff of the Department of Parasitology, University of Chicago, for their opinion in regard to this species of *Microfilaria*, and to Dr. Porter B. Lennox of the Department of Pathology, School of Medicine, Howard University, for taking and developing the photomicrographs.

## THE TOXIN OF BACILLUS PROTEUS\*

HOWELL RANDOLPH, M.A., M.D., PHOENIX, ARIZONA

THE toxic properties of cultures of proteus isolated from various sources has been the subject of considerable study since the time of Hauser's<sup>1</sup> original description of the type organism of the proteus group when he demonstrated its pathogenicity for animals.

That both solutions of the dried, sterile, powdered organisms and filtrates from cultures have definitely toxic effects has been repeatedly demonstrated, and Bengston<sup>2</sup> in summarizing the results of the work in this field states that "*B. proteus vulgaris* produces a weak soluble toxin, as compared with tetanus and diphtheria."

However, while agglutinins have been demonstrated in high dilutions following immunization and in infections with the organism, and while a relative immunity to the usual fatal doses has been produced, there seems to have been only one demonstration of an antitoxin. Herter and Ten Broeck<sup>3</sup> were unable to establish immunity to the toxic extracts of the powdered organisms.

Isabolinski and Judenitsch<sup>4</sup> succeeded in preparing two culture filtrates containing immunizing antibodies of different degrees of effectiveness. The cultures were obtained from patients suffering from typhus fever and were grown on agar plates and in broth. The "H" form contained more immunizing substances than the "O" form, as shown on rabbits receiving lethal doses of the original culture.

I have investigated the subject of antitoxin production in rabbits and attempted to form some idea of the relative toxicity of the filtrates for man.

The strain of proteus employed was isolated from catheterized bladder and ureteral urine from a girl, twenty years old, with uncomplicated pyelitis due to proteus.

The organism was a small gram-negative rod, motile in young cultures, gradually losing motility after the first twenty-four hours. On agar it spread rapidly over the plates forming a thin gray film, covering the plate from four to five streaks in twenty-four hours. It grew more rapidly on blood agar than plain. It liquefied gelatin, naptiform in twenty-four hours, and complete in from three to four days at room temperature. Litmus milk was changed to acid and coagulated in from two to three days, peptonized and alkaline in five days. Nitrites were formed. No indol was produced. Acid and gas are formed in dextrose, galactose, levulose and saccharose (after three days). No acid or gas was produced on lactose, maltose, raffinose, arabinose, mannitol, dulcitol, dextrin, glycerol, salicin, sorbitol and inulin. Sugar mediums were prepared by adding 5 per cent sugar to broth containing 1 per cent Liebig's meat extract 5 per cent Witte's peptone, and sodium chloride 5 per cent.

\*From the John McCormick Institute for Infectious Diseases, Chicago.  
Received for publication, August 3, 1933.

Plain broth mediums, as used in fermentation tests, titrated to  $P_H$  6.0 were used for growing cultures in preparation of the filtrates. Cultures were incubated from one to eleven days at  $37^\circ C$ . Each culture was checked for contamination before filtering. Berkefeld "X" filters were used for the first filtration; the filtrate was then passed through "W" filters and tested for sterility by both aerobic and anaerobic methods, culturing on blood agar slants.

#### EFFECT UPON RABBITS

The rabbits used were young and weighed between 1,500 and 2,000 gm., averaging about 1,700 gm. The filtrate was injected, unless otherwise specified, into the marginal ear vein.

Ten cubic centimeters of the filtrate of a one-day culture caused no apparent ill effect. Ten cubic centimeters of the filtrate of a three-day culture caused death in less than twenty-four hours. The same dose of the filtrate of a five-day culture failed to kill another rabbit but produced severe illness with diarrhea and moderate loss of weight. Five cubic centimeters of the filtrate of an eight-day culture caused death in less than twenty-four hours and in 6 rabbits all doses above this were fatal in less than twenty-four hours. Doses

TABLE I

THE EFFECT UPON RABBITS OF FILTRATES OF CULTURE GROWN FOR VARYING LENGTHS OF TIME WITH VARIATIONS IN THE DOSAGE. INTRAVENOUS ADMINISTRATION

| RABBIT | DOSE IN C.C. | AGE OF CULTURE         | RESULT                                                                                                                                             |
|--------|--------------|------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------|
| 1      | 11           | Broth control          | No ill effects.                                                                                                                                    |
| 2      | 10           | 1 day                  | No ill effects.                                                                                                                                    |
| 3      | 10           | 3 days                 | Died in less than 18 hours. Heart's blood sterile. This rabbit had received 10 c.c. of broth control two days before without apparent ill effects. |
| 4      | 10           | 5 days                 | Diarrhea for four days, loss of 250 gm. Recovery.                                                                                                  |
| 5      | 5            | 8 days                 | Died in less than 18 hours.                                                                                                                        |
| 6      | 9            | 11 days                | Very ill next day. Emaciation with loss of considerable weight. Died in 16 days.                                                                   |
| 7      | 5            | 11 days                | Died in less than 18 hours.                                                                                                                        |
| 8      | 10           | 11 days                | Died in less than 18 hours.                                                                                                                        |
| 9      | 10           | 11 days                | Died in less than 18 hours.                                                                                                                        |
| 10     | 10           | 11 days                | Died in less than 18 hours.                                                                                                                        |
| 11     | 10           | Broth control          | No ill effects.                                                                                                                                    |
| 12     | 10           | Broth control          | No ill effects.                                                                                                                                    |
| 13     | 1½           | 11 days                | Died in two days; 13 c.c. of blood had been withdrawn 2 days before without apparent ill effects.                                                  |
| 14     | 1            | 11 days                | Died in 24 hours; 13 c.c. of blood had been withdrawn 2 days before without apparent ill effects.                                                  |
| 15     | 2            | 11 days<br>(3 mo. old) | Lost 330 gm. in 4 days. Diarrhea was present on the first day and more marked on the second. Lost 610 gm. in 7 days.                               |
| 16     | 2            | 11 days<br>(3 mo. old) | Found dead in less than 15 hours.                                                                                                                  |

of  $\frac{3}{4}$  to 2 c.c. of a three-month-old filtrate killed 3 rabbits and produced severe illness in another. Doses of  $\frac{3}{4}$  c.c. and  $1\frac{1}{2}$  c.c. killed 2 rabbits from which 10 c.c. of heart blood had been withdrawn two and nine days before, respectively.

One rabbit recovered from intramuscular injection of 5 c.c. of toxin which, when injected intravenously, killed rabbits of the same weight when administered in doses of less than 2 c.c. The rabbit injected intramuscularly, however, was sick and lost 20 per cent of its weight.

To determine the toxin production in gelatin, cultures were grown for six weeks at room temperature, diluted with salt solution in proportion 1:4 and filtered as described for broth filtrates;  $1\frac{1}{2}$  c.c. of this dilution killed a rabbit in less than twenty-four hours. One cubic centimeter caused profound illness, with loss of 29 per cent of weight in three days. Control gelatin produced no ill effects.

The results (Table I) demonstrate that less than 5 c.c. of filtrate from the eleven-day broth is usually a fatal dose for a rabbit weighing between 1,500 and 2,000 gm. Doses of 2 c.c. or less caused either death or profound illness. Doses of 10 c.c. always killed in less than twenty-four hours.

#### TOXIC EFFECTS

The most characteristic reaction to the filtrate was diarrhea, the entire contents of the small and large intestines being liquid, with marked distention. Microscopically there was a marked infiltration of the submucosa with leucocytes and lymphocytes, also hyperemia. The mucosa showed areas of sloughing and necrosis of the tips of the villi (postmortem). The Peyer's patches were frequently enlarged.

The kidneys were dark purplish red and showed areas of hemorrhagic infiltration with cloudy swelling of the cortex.

The liver was somewhat enlarged, but usually it showed no marked microscopic changes.

The heart was usually dilated and filled with a blood clot, the muscle being thin and flabby. Microscopically there were small areas of parenchymatous degeneration.

Blood cultures were uniformly sterile; urine cultures showed no proteus; *B. coli* was present twice; and spore formers, once or twice.

#### ANTITOXIN PRODUCTION

Five normal rabbits were selected and their serums tested for ability to protect other rabbits. Five cubic centimeters of their serum were allowed to stand at room temperature with 10 c.c. of the toxin onehalf hour before injection intravenously. (Table II.)

Four of the 5 died quickly. The fifth survived after severe illness.

To 3 of the rabbits from which serum had been tested, 7 weekly doses of eleven-day filtrate, increasing from 0.2 c.c. to 6 c.c. were given intramuscularly without apparent ill effects or loss of weight except slight diarrhea for two

EFFECT OF INJECTION OF TOXIN FROM ELEVEN-DAY BROTH CULTURES WITH SERUM FROM NONIMMUNIZED RABBITS

| SERUM FROM RABBIT NUMBER | C.C. OF SERUM | C.C. OF TOXIN | RESULT                                                                             |
|--------------------------|---------------|---------------|------------------------------------------------------------------------------------|
| 1                        | 10            | 10            | Very weak; lay on side; temperature, 105° F. Loss of 680 gm. in 14 days. Recovery. |
| 2                        | 4½            | 9             | Died in 48 hours.                                                                  |
| 3                        | 5             | 12            | Found dead in less than 18 hours.                                                  |
| 4                        | 4             | 7½            | Found dead in less than 18 hours.                                                  |
| 5                        | 5             | 11            | Died with marked emaciation in 8 days.                                             |

days in one, following the fourth dose. The fourth rabbit was given similar increasing doses of broth.

Eleven days after the last dose, the serum was tested again. (Table III.)

TABLE III

EFFECTS OF INJECTION OF ELEVEN-DAY TOXIN WITH SERUM FROM RABBITS WHICH HAD BEEN IMMUNIZED BY SEVEN INTRAMUSCULAR WEEKLY DOSES OF TOXIN, THE CONTROL RECEIVING THE EQUIVALENT DOSE OF BROTH

| SERUM FROM RABBITS | C.C. OF SERUM | C.C. OF TOXIN | RESULT                                                                                                    |
|--------------------|---------------|---------------|-----------------------------------------------------------------------------------------------------------|
| Immune, A          | 4             | 10            | Slight diarrhea next day. Lost 200 gm. in 5 days. Well. Never weak.                                       |
| Immune, B          | 4             | 10            | Died in less than 18 hours.                                                                               |
| Immune, B          | 4             | 10            | Lost 260 gm. in 3 days. Snuffles appeared on the third day. Recovery.                                     |
| Immune, C          | 4             | 10            | Slight diarrhea. Lost 240 gm. in 3 days. Not very ill. Began to gain on third day. 1590 gm. on fifth day. |
| Control            | 4             | 10            | Died in less than 18 hours.                                                                               |
| Control            | 4             | 10            | Died on third day, severe diarrhea.                                                                       |

In 3 rabbits more than three times the lethal amount of toxin was neutralized by 4 c.c. of immune serum. In one case 4 c.c. of immune serum failed to protect, but a second rabbit, after receiving the same amount of this anti-serum and filtrate showed only moderate loss of weight with slight diarrhea and recovered.

Four cubic centimeters of the serum from the rabbit injected with broth failed to protect in 2 rabbits, one dying in twenty-four hours, the other in three days.

#### SKIN TESTS

The results of intradermal tests on rabbits show first that susceptibility to the filtrate is comparatively low. However, of 13 rabbits tested, all but one reacted positively to the undiluted toxin, and in this one the reaction area was almost up to the 1 cm. diameter taken as a minimum standard for a positive reaction.

Seven of the 13 rabbits were positive in dilution of 1:10, the reaction being less than 2 cm. in diameter in all but one.

Two of the 4 rabbits, given increasing intramuscular injections of the filtrates weekly for six weeks, reacted negatively to undiluted toxin after

having been positive to 1:10 dilution before immunization. The other two showed definite diminution in the intensity of the skin reaction.

Two rabbits which had been given transient bladder infections with the organism two months before reacted positively to a 1:10 dilution in the skin test.

To test the toxicity of the filtrate for man, preparations as described were diluted with normal salt solution, and the reaction of the skin to intradermal injections of 0.1 c.c. of various dilutions was observed eighteen and twenty-four hours later. A reaction area measuring  $1 \times 1$  cm. or more, from eighteen to twenty-four hours after injection was considered a positive test.

In susceptible persons, redness appeared at the site of injection shortly after the test was made, fading in an hour or less. About four or six hours later pinkness the size of the welt was present and gradually increased in size and intensity to its maximum which might be reached in six or eighteen hours; it usually began to fade after about twenty-four hours and disappeared in from forty-eight to seventy-two hours. With well-marked reactions the color on the second day was brownish red fading to brown. If the reaction was fairly intense, from slight to moderate induration was present with elevation at the site of injection.

Freshly filtered and diluted toxin was found to give a positive test in 1 of 2 adults and 4 of 13 children (from three to six years old) in a dilution of 1:255,000. The reactions were faint. This solution was found to deteriorate rapidly, two weeks later giving a negative test in the previously positive persons.

Tests made at intervals during four and one-half months with 1:5,000 dilutions were positive. The last tests were about two-thirds the size of the first, indicating a slight deterioration at ice box temperature.

The solution, heated for one hour at  $100^{\circ}$  C., was used as control and was found to give only slight redness at site of injection, or negative tests. Test solution heated for two hours at  $100^{\circ}$  C. showed no redness at site of injection in twelve cases reacting positively to the unheated toxin and faint reactions a centimeter or less in diameter in two cases.

Strains of the organism kept on blood agar for three months retained the ability to produce a highly toxic filtrate. One such filtrate (eleven-day culture) gave a positive skin reaction in one and a negative skin test in 2 adults in dilution of 1:50,000. This filtrate two months later gave a negative test in the susceptible person in dilution 1:20,000, but was positive in dilution 1:10,000 and strongly positive in dilution 1:5,000. The skin test area was slightly larger in the case of this filtrate than in that from the freshly isolated strain.

#### CONCLUSIONS

*B. proteus* produces a toxin, the toxicity of the filtrate increasing with the age of the culture. Toxin production is about four times as great in gelatin as in peptone broth. The sterile toxin injected intravenously into rabbits causes diarrhea, loss of weight, and death.

Neutralization of this toxin in vitro by blood serum from rabbits immunized with it indicates that it is a soluble exotoxin capable of producing an antitoxin in rabbits.

Toxin solutions deteriorate on standing at ice box temperature and more rapidly at higher dilutions. The toxin is fairly stable in undiluted form. *B. proteus* cultures kept on artificial mediums for three months do not lose the ability to produce toxin.

Skin tests made with various dilutions of the toxin indicate that man is much more susceptible than the rabbit.

PROFESSIONAL BUILDING

## COCAINE POISONING AS INFLUENCED BY DIETS\*

### PRELIMINARY REPORT

A. J. NEDZEL, M.D., CHICAGO, ILL.

THE influence of diets, especially with alkalinizing and acidifying tendency, has been previously studied, particularly in connection with phosphorus poisoning. We have been interested in altering the acid-base balance of rabbits as a basis for studies in connection with seasonal diets and climatic changes. Hoping that we may find, in certain drugs, reagents that might help us in this study, we undertook feeding experiments upon rabbits, intended to alter their acid-base equilibrium, and then injected in these animals toxic doses of cocaine. The results have been sufficiently striking to make this preliminary report seem desirable.

We have used in these experiments various diets that will promote a prevalence of acids or bases in animals in the normal physiologic limits without causing any noticeable pathologic changes in them.

Forty-eight experiments were performed on thirty rabbits. These experiments were divided into three series of sixteen each. In each series, before the performance of an experiment, the animals were kept on certain diets for a period of three weeks. In the first series, the animals were kept on oatmeal

\*From the Department of Bacteriology and Preventive Medicine, and the Department of Pharmacology, University of Illinois, College of Medicine.  
Received for publication, August 15, 1933.

and water; in the second series, on carrots; and, in the third, on oatmeal, water, and carrots. During the dieting the urine of the animals was tested daily for its reaction (Folin's method). From the second week on the urine of rabbits of the first series of experiments showed distinct and stable acid reaction (from 14 to 60); the urine of the animals of the second series was persistently alkaline; and that of the third series, slightly alkaline or neutral. In the third series of experiments, the same eight rabbits were used twice; the animals of the first and second series of experiments were changed from one diet to another. Ten rabbits withstood these experiments and were on both diets, and six succumbed, so that the latter had to be replaced by new animals.

The experiments consisted of injections of cocaine into the marginal ear vein of a rabbit. The injections were performed uniformly, the duration of

Chart 1.—The perpendicular line shows the number of rabbits. The columns on the horizontal lines are grouped by the time that elapsed from the moment of cocaine injection (1, 2, 4, 7, 10, 15, 20, 30, 45, and 60 minutes) and represent the degree of reactions (see chart) and number of animals. Each group of columns represents the same animals, reacting differently at various time intervals. The animals that died or recovered at certain times of observation are not shown in the following column.

injection being about 10 seconds. The dose of cocaine was 10 mg. per kilo. After injection, the animal was observed as long as symptoms were manifest. The degree of intoxication was recorded by checking the (1) death, (2) convulsions, (3) complete prostration without convulsions, (4) recovering (crawling, lifting head), and (5) recovery. Before the injection of cocaine a certain amount of blood was withdrawn from the ear vein and tested for its hydrogen ion concentration. The average  $P_H$  of the blood of the rabbits on acid diet was 7.301, on alkaline diet 7.426, and mixed diet 7.423, which showed that the rabbits in our experiments were within the limits of the normal acid-base balance.

The results are presented in Chart 1.

The described observations permit us to arrive at the following conclusions:

1. The animals on alkaline-forming diet and on mixed diet reacted to the injection of cocaine, more or less similarly; though the animals on the alkaline diet reacted more vigorously, since we recorded two deaths in this series.

2. The animals on acid-forming diet were definitely more sensitive to cocaine poisoning. Here were recorded four deaths; and, in general, the toxic effects of the cocaine were definitely greater and recovery was considerably delayed.

3. The observations presented suggest the investigation of a number of other powerful drugs in connection with their action upon the animal organism in various states of acid-base balance. Only then would it be permissible to speculate upon the reason for the difference noted.

4. It may be possible, that, in acute cocaine poisoning, the intravenous injection of alkali might be of benefit for the poisoned individual; and experiments upon animals, to test this question, are called for.

## NASOPHARYNGEAL FLORA AND SOME REMARKS AS TO THEIR RELATION TO COMMON COLDS\*

---

K. YARDUMIAN, M.D., AND ESTELLE LOGAN LIGHTNER, B.S., PITTSBURGH, PA.

---

THE common cold is generally defined as an acute or subacute infection of the mucosa of the nasopharynx, often invading the sinuses and occasionally the middle ear through the eustachian tube. At times, it may also extend through the trachea, larynx, and bronchial tree. Furthermore, it may leave a chronic condition locally or elsewhere.

Although the common cold is considered the mildest and least serious of all known common diseases, yet it is most frequent, annoying, and depressing; and it often results in the lowering of resistance of the individual, thus making him prey to more serious diseases. Generally speaking, no one is exempt from attacks of colds. Some have occasional attacks, others frequent attacks. One may have mild infection, while others have severe ones. In either case, it lessens the efficiency of the worker, resulting in great total loss economically.

A tremendous amount of experimental and research work is carried on concerning common colds, both in this country and abroad. Medical periodicals have published voluminous articles on etiology, pathology, and treatment of this condition. Unfortunately, it seems we are still wandering in the dark and very little has come to light which points to a definite conclusion about this common ailment.

In reviewing the literature on this subject, within the last few years, one

---

\*From the Montellere Hospital, Department of Pathology, Isaac Kaufmann Foundation. Received for publication, August 16, 1932.

finds that quite a few well-outlined and definite studies have been carried on by various workers. I will quote briefly the conclusions of some of the papers:

From their cultural studies of nose and throat of 105 adults and children, Webster and Hughes<sup>1</sup> isolated pneumococci in 80 per cent of cases, and out of 500 pneumococcic strains 97 per cent were serologically specific. Successive cultures from given carriers, with rare exceptions, had a constant serologic type and were similar in type of colonies, morphology, virulence for mice, and in other biologic characteristics. They conclude also that the incidence of pneumococci in all individuals studied undergoes seasonal variation paralleling that of coryza and sore throat in the same person. Third, some patients were pneumococcus-free; some were transient carriers; some periodic, and others chronic carriers. The data suggest that these differences are due to variations in the host resistance.

According to the observations made by Webster and Clow<sup>2</sup> of the association of pneumococci, *Hemophilus influenzae* and *Streptococcus hemolyticus* with coryza, pharyngitis, and sinusitis in man, they came to the conclusion that persons free of those organisms mentioned above are, in general, free of coryza, sore throats, influenza, and sinus diseases. Also they found that persons who are occasional or periodic carriers of these organisms may be negative on tests carried out during long healthy periods, but that they generally become positive during or following attacks and subsequently become negative again with returning health.

Third, their data suggest that persons who are chronic carriers show during these illnesses an increase in the number of organisms in the throat and wider distribution of these organisms in the air passages. These observations bring out the intimate relationship between pathogenes of upper respiratory diseases and their symptoms, but they do not disclose the actual nature of this relationship.

In their experimental studies of the common cold, Dochez, Shibley, and Mills<sup>3</sup> state that in both spontaneous and in experimentally induced colds in anthropoid apes, the most significant change that occurs is the increase of activity on the part of the potential pathogenes habitually present in the throat flora. Coincidentally, with the appearance of symptoms, they found that pneumococci, *Streptococcus hemolyticus* and Pfeiffer's bacillus developed in greatly increased numbers and spread over wide areas of nasopharyngeal membranes. These organisms become, after a time, conspicuous in the nose where they are seldom or never present under normal conditions. This has also been observed in human beings. Furthermore, they emphasize the fact that these organisms are secondary invaders and that the most significant factor in common cold pathogenesis seems to be their capacity to incite greater activity on the part of the more dangerous pathogenic organisms which infect the upper respiratory tract.

D. Thompson and R. Thompson,<sup>4</sup> in an extensive article, stress several points on common colds; that the common cold is not a definite single disease, but a group of diseases caused by several different species of organisms and other factors. According to their classification, colds are divided into three groups: (1) bacterial; (2) allergic; and (3) virus colds.

The bacterial flora of the healthy respiratory tract is plentiful and in great variety but has not been thoroughly worked out and classified. The streptococcus is the most common organism of any virulence generally found; next in frequency of occurrence are the pneumococci and *B. influenzae*.

The following are observations made in infants over a period of two years by Kneeland and Dawes.<sup>5</sup> In two severe winter outbreaks of respiratory infection, a parallel rise in carriers of pathogenic organisms was noted. The first autumn outbreak of colds seemed to provide the dissemination of pathogenic organisms. The relationship of colds to the more severe infections was roughly reciprocal. The peak of the carrier rate was reached in March. It seemed that *Hemophilus influenzae* was more predominant in the first year, and pneumococci, in the second year of the study.

Recent studies of filtrable viruses as etiologic factors of colds, by Dochez, Shibley and Mills<sup>6</sup> suggest that the contagious cold in human beings is caused by an invisible and unculturable, filtrable agent which, in all likelihood, belongs to the group of so-called submicroscopic viruses. Colds can be transmitted successfully, they state, from man to chimpanzee and from man to man by means of Berkefeld filtrates of nasal washings obtained from individuals suffering with spontaneous colds, more especially during the period of rising incidence of infection in the community. This experimental cold resembles in all respects those spontaneously contracted in the natural environment.

Cultivation of the virus of the common cold by Powell and Clowes<sup>7</sup> implies, according to their work, that 80 per cent of subjects used experimentally contracted inoculated colds. No subjects were used except those who had no history of colds for two months and showed records of two or three colds per year. They were inoculated during that period of the year when colds were not prevalent. This verified the conclusion of Dochez that the virus of the common cold is easily cultivated in an appropriately prepared chick embryo and is readily transmitted to human subjects.

Burkey and Freese<sup>8</sup> lay claim to isolating a gram-negative filtrable anaerobic organism in 92 out of 114 examinations of individuals in widely separated communities. Positive cultures were obtained from persons with or without colds both during the acute and the later stages of the disease. The strains which were cultivated were prevalent in normal throats as well as in the nasopharynxes of persons suffering from colds at the time. More satisfactory results were obtained in filtering the nasopharyngeal washings through a Berkefeld V-filter. This series of examinations was too small to lead to definite conclusions. The results indicate, however, the presence of these organisms in material from the mouth as well as the pharynx.

In studies concerning the prevention and treatment of colds with vaccine, Murray<sup>9</sup> compared a group of 85 persons who were 100 per cent susceptible to colds with a group of uninoculated controls, within a period of six months covering the seasons of prevalence of colds. Figures and clinical experience with a mixed catarrhal vaccine in that clinic have shown that vaccine therapy offers as much, if not more, than any other preventive measure that has been tried against colds. It is well worth the while to try this type of preventive measure in persons susceptible to colds.

Three years of experience with stock vaccine in colds and in the prevention of respiratory disorders, according to one observer in the literature, indicated that the value of stock vaccines varies with the individual subjected to the therapy.<sup>10</sup>

The purpose of our study was:

(a) To isolate the organisms in the nose and throat of individuals having frequent colds, during the acute attack.

(b) To study in a like manner a number of individuals without colds, or relatively immune to colds.

(c) To carry through parallel cultures of these organisms in hormone broth and in the blood of the subject.

(d) To prepare vaccines from these growths found in the autogenous blood and to attempt the immunization of the subjects with these vaccines.

(e) To attempt, incidentally, to determine the effects of tonsillectomy on the frequency of colds.

These studies were carried out on patients visiting the Out-Patient Department of the Montefiore Hospital. Cultures were taken from 200 patients. From these, 100 were chosen as controls because they had had no colds for a long period of time. The other 100 patients gave histories of frequent colds throughout the year. A few of these complained of regular seasonal colds. In this series 82 were males and 118 females; 64 had had tonsillectomy; 136 had tonsils intact.

The culture technic was carried out as follows: The throat of each patient was rinsed with sterile salt solution. A cotton swab was then rubbed against the pharyngeal wall and a second swab was contaminated in the nostril. Special care was taken not to contaminate the swab by touching the floor of the mouth. These swabs were placed in nutrient broth, incubated for from 24 to 48 hours, and subcultured on blood agar plates. Parallel with these broth cultures, swabs treated as described above were placed in from 3 to 5 c.c. of fresh whole blood obtained from the patient's vein. After 24 hours of incubation, a drop of this blood was plated and the colonies resulting were identified.

Finally, vaccines were prepared from the organisms isolated in the autogenous blood cultures and the patients who were highly susceptible to colds were inoculated. The technic of preparation of the vaccine was as follows: A 48-hour growth of the organism isolated in the autogenous blood medium in each case and subcultured on hormone broth was treated chemically, utilizing saturated trichresol solution, giving a final dilution of 0.5 per cent trichresol in the vaccine. In 48 hours this was tested for sterility. The vaccine was administered in a starting dose of 1 ml twice a week and was progressively increased to a maximum of 15 ml twice a week. With this technic, the patient received the benefit of the activity of both the bacteria and its elaborated toxin in broth media. Patients who were highly susceptible to colds were inoculated with vaccines prepared according to the method just mentioned. The number of patients that received regular treatments thus far was only seventeen, and it is hardly fair to draw final conclusions. Ten

of seventeen showed relief from colds thus far, and the rest had marked improvement; the frequency and severity were markedly diminished. Final report will be given at the end of treatments administered to a hundred or more cases.

Results of the studies:

(a) The cultures in hormone broth generally showed a mixed growth of various organisms. Staphylococci, streptococci, pneumococci, *Micrococcus catarrhalis*, and unidentified gram-positive and gram-negative cocci and bacilli.

(b) Cultures in autogenous blood media generally showed a single organism, but occasionally more than one.

Incidence of various bacteria in broth culture and in autogenous blood cultures.

TABLE I  
TWO HUNDRED CULTURES FROM NASOPHARYNGES IN AUTOGENOUS BLOOD

| ORGANISM                       | NUMBER | PERCENTAGE |
|--------------------------------|--------|------------|
| Staphylococci                  | 126    | 63         |
| Streptococci                   | 78     | 39         |
| Pneumococci                    | 64     | 32         |
| <i>Micrococcus catarrhalis</i> | 8      | 4          |
| Gram-positive bacilli          | 12     | 6          |
| Gram-negative bacilli          | 4      | 2          |
| Sterile                        | 40     | 20         |

TABLE II  
ONE HUNDRED CULTURES FROM NASOPHARYNGES OF PATIENTS FREE FROM COLDS

| ORGANISM                       | BROTH MEDIUM | AUTOGENOUS BLOOD |
|--------------------------------|--------------|------------------|
| Staphylococci                  | 55           | 51               |
| Streptococci                   | 53           | 41               |
| Pneumococci                    | 52           | 38               |
| <i>Micrococcus catarrhalis</i> | 45           | 4                |
| Gram-positive bacilli          | 10           | 4                |
| Gram-negative bacilli          | 45           | 5                |
| Sterile                        | 0            | 10               |

TABLE III  
ONE HUNDRED CULTURES FROM NASOPHARYNGES OF PATIENTS SUSCEPTIBLE TO COLDS

| ORGANISM                       | BROTH MEDIUM | AUTOGENOUS BLOOD |
|--------------------------------|--------------|------------------|
| Staphylococci                  | 64           | 63               |
| Streptococci                   | 50           | 39               |
| Pneumococci                    | 38           | 31               |
| <i>Micrococcus catarrhalis</i> | 22           | 4                |
| Gram-positive bacilli          | 11           | 6                |
| Gram-negative bacilli          | 5            | 2                |
| Sterile                        | 0            | 21               |

Analysis: Tables II and III may be compared. The former applies to the 100 controls who were, as stated, free from colds. The latter is descriptive of the flora found in 100 patients who were susceptible to colds. The highest number of cultures showed staphylococci, considering the entire 200 cultures. Next in the same group we found streptococci and pneumococci to be most numerous, in the order named. It should be noted also that 20 per cent of the cultures carried out on autogenous blood remained sterile. From the comparative study of these tables, it is easily seen that those organisms grown on broth and unidentified failed to grow in the autogenous blood medium.

According to the theory propounded by Dr. Meyer Solis-Cohen and coworkers<sup>11</sup> an organism is pathogenic to the individual only if it is grown in his blood; and failure to do so indicates resistance in the individual to the organism. His findings, further, have been confirmed by others; notably Bull and Bartual,<sup>12</sup> Black, Fowler and Pierce,<sup>13</sup> Smiley,<sup>14</sup> and T. Matsunami and J. A. Kolmer.<sup>15</sup>

#### CONCLUSIONS

1. Individuals who are free from colds, and those who have frequent colds show no notable difference from each other in their nasopharyngeal bacterial flora.

2. The resistance of the individual is probably a more important factor in susceptibility to colds than is the nasopharyngeal bacterial flora.

3. Vaccines prepared from cultures of organisms of the nasopharyngeal flora on autogenous blood media (pathogen selective) appear to have given relief from the tendency to the common cold in 59 per cent of the cases.

# LABORATORY METHODS

## A SIMPLIFIED MICRODETERMINATION OF CHOLESTEROL IN WHOLE BLOOD, SERUM, AND PLASMA\*

JONAS KAMLET, B.Sc., BROOKLYN, N. Y.

THE basis of all colorimetric methods for the determination of cholesterol is the Liebermann-Burchard reaction, which is conducted on an anhydrous chloroform solution of the blood cholesterol. Bloor<sup>1</sup> obtains this by extracting the cholesterol with hot alcohol ether, evaporating the solvent and dissolving the residue in chloroform. This method, especially in the micromodification of Sackett<sup>2</sup> is most widely used in clinical laboratories. Other methods dry the blood on plaster of Paris at 100° C. (Myers and Wardell<sup>3</sup>) or on filter paper in air (Ling<sup>4</sup> and Leiboff<sup>5</sup>) and extract with hot chloroform in special continuous extraction apparatus.

The use of heat occasionally produces a brownish off-color tinge in the unknown, which renders colorimetric comparison difficult. We therefore tried to determine if the extraction of the cholesterol may be effected at room temperature without the use of complicated extraction apparatus. Preliminary experiments showed that the cholesterol is quantitatively extracted by chloroform from blood dried on filter paper in two hours at room temperature. Therefore, the following procedure was adopted for the determination of cholesterol in blood.

### PROCEDURE

On an ordinary 7 cm. filter paper, preferably ashless, deposit 0.2 c.c. of oxalated blood, serum, or plasma. Work the paper around until the liquid is distributed fairly evenly over the surface and then suspend it by means of a thread or wire strung through an unstained area in an incubator at from 35° to 40° C. After from twenty to thirty minutes the blood is completely dried. Roll the paper up compactly; fold into quarters and deposit it in the bottom of an ordinary 6 inch × 1 inch test tube. Into the tube, pipette 10 c.c. of chloroform; cork, and set aside for at least two hours. During this period the chloroform should completely cover the folded filter paper. In this manner a quantitative extraction of cholesterol from dried blood, serum, or plasma is effected without the use of heat, thus avoiding the occasional appearance of an off-color. Now, pipette 5 c.c. of the chloroform solution into an ordinary test tube. Into a similar tube place 5 c.c. of the working cholesterol standard.<sup>†</sup>

\*From the Department of Laboratories, Israel Zion Hospital.

Received for publication, August 11, 1933.

†Stock Cholesterol Standard: Dissolve 1 gm. C.P. cholesterol in chloroform to make 100 c.c. of solution.

Working Cholesterol Standard: Dilute 5 c.c. of the stock cholesterol standard with chloroform to make 1000 c.c. of solution; 1 c.c. contains 0.95 mg. cholesterol. Both standards keep indefinitely in a refrigerator.

To each tube add 2 c.c. of acetic anhydride and 0.2 c.c. of concentrated sulphuric acid. Stopper, mix by inversion and allow to stand for fifteen minutes in a cool, dark place. Compare in the colorimeter.

Comparison:

$$\frac{\text{Reading of standard}}{\text{Reading of unknown}} \times 250 = \text{mg. cholesterol per 100 c.c. blood.}$$

Set unknown at 25 mm. and compare. The reading of the standard multiplied by ten gives the milligrams of cholesterol in 100 c.c. of whole blood, serum, or plasma.

This method is especially suited for use in clinical laboratories where the determination of cholesterol is conducted as part of a routine. The blood may be dried and allowed to extract with chloroform while the remainder of the routine is carried on. The actual working time per determination is from four to five minutes.

This procedure was conducted on 125 specimens of blood, serum, and plasma ranging in cholesterol content from 76 to 585 mg. per 100 c.c. and checked by the Bloor-Sackett method. In all cases, the results obtained agreed within 9 mg. per 100 c.c. with an average difference of 3.55 mg.

#### SUMMARY

Blood is dried in air on filter paper, extracted with chloroform at room temperature for at least two hours, and the Liebermann-Burchard reaction is conducted on the extract.

## EXAMINATION FOR TUBERCLE BACILLI<sup>2</sup>

MARY VAN S. MCCOY, NEW YORK, N. Y.

KOERTH and Hibbard<sup>1</sup> have recently reported a comparison of methods for staining tubercle bacilli, based on the use of three stains. They claimed better than 25 per cent advantage for the Spengler stain over the Ziehl-Neelsen method. The Schulte-Tigges method, though nearly as efficient as the Spengler by their test, was ruled out as more difficult and more subject to errors in technic.

We have examined one hundred sputums chosen at random, except that they had been reported negative or contained less than six bacilli with the Ziehl-Neelsen technic. Fifty were twenty-four-hour specimens, the other fifty being collections over a period of three days.

When the results were being tabulated, it was found that seventy-one patients were represented, covering all stages of the disease. A large number had never given a positive sputum by direct smear, nor had guinea-pig inoculations proved a diagnosis of tuberculosis on many of them.

A five-minute time standard was used. By "positive" is meant that six or more bacilli were found during this period. In a "negative," no bacilli were found during a five-minute search. If less than six bacilli were seen during the five-minute interval, the number is given.

The results are shown in the following table:

| STAIN         | NEGATIVE | POSITIVE, MORE<br>THAN 6<br>BACILLI | LESS THAN 6<br>BACILLI† | NUMBER OF<br>SLIDES SHOWING<br>BACILLI |
|---------------|----------|-------------------------------------|-------------------------|----------------------------------------|
| Ziehl-Neelsen | 95       | 0                                   | 5                       | 5                                      |
| Spengler      | 85       | 10‡                                 | 5                       | 15                                     |

†Not recognized as positive by some authorities.

‡Five of these positives were those specimens where less than six bacilli were found by the Ziehl-Neelsen method. The Spengler simply increased the number.

The conclusion is drawn in favor of the Spengler method. We have also found the method satisfactory in tissue staining.

A second study was made on the comparative value of two concentration methods, the hydrogen peroxide<sup>2</sup> and the antiformin method.<sup>3</sup>

Here, too, the series was short. Examinations were made of some twenty cases which had given negatives in from one examination to examinations covering several months. Some had never given a positive.

Except when guinea pigs were to be inoculated, the tests were made on sputum sterilized by autoclave. Controls of known positives, both sterile and unsterile, were used by both methods. Tubercle bacilli found in the glands

<sup>2</sup>From the Grasslands Hospital, Valhalla, New York.  
Received for publication July 15, 1933.

and spleen of an inoculated guinea pig proved that the organism remained viable after being subjected to the hydrogen peroxide treatment.

The two procedures checked closely, one more positive slide being found by the peroxide concentration than by the antiformin method. As this procedure was much less time consuming, making it possible to report the result of an examination on the day the specimen was received, it was chosen as our routine. In a group of two hundred specimens (all of which had been negative at the examination immediately preceding) treated by this method and centrifuged fifteen to thirty minutes at fairly high speed, we were able to report thirty-one positives and the presence of a few bacilli (less than six) in four other cases. This made thirty-five concentrations, or 17.5 per cent, showing organisms when from one to many previous examinations had been negative.

## HEMOGLOBIN AND BLOOD CELL RELATIONS AS DETERMINED BY IRON AND OXYGEN CAPACITY METHODS\*

---

G. O. BROUN, M.D., AND A. P. BRIGGS, M.D., ST. LOUIS, MO.

---

IN A recent article Haden<sup>3</sup> has summarized the various methods employed for the determination of hemoglobin and the present state of knowledge regarding the normal hemoglobin content of blood. He points out a certain lack of agreement in the three largest series of determinations of hemoglobin in normal men and women. The oxygen capacity hemoglobin method of Van Slyke was the basis of comparison in the series quoted, namely, those of Osgood,<sup>5</sup> Wintrobe and Morell,<sup>8</sup> and Haden.<sup>4</sup> The absence of any large series of hemoglobin determinations in normal individuals in which iron determinations are used as the basic method is noted by Haden and also pointed out as desirable by Peters and Van Slyke.<sup>6</sup>

We are, accordingly, reporting hematologic studies on a number of patients and normal individuals of both sexes, in which the hemoglobin determinations were based both on the oxygen capacity and the iron content of blood.

Most of the individuals examined lived in or near St. Louis, although some were medical students who had spent the greater part of their lives in other localities in this country. Twenty-three normal men and thirteen normal women were studied. In addition observations were made on thirty patients ill with various conditions.

solution was made for enumeration of blood cells. The count reported represents the average of four to eight fills of the counting chamber. Bureau of Standards equipment was used. Hematocrit determinations were made in duplicate after saturating with oxygen in sedimentation tubes and centrifuging to constant values.

The oxygen capacity method used was that of Van Slyke and Neil.<sup>7</sup> Hemoglobin determinations based on iron were made by two separate technics recently devised in this laboratory.<sup>1</sup> In one hemoglobin was calculated from a colorimetric estimation of protein iron as Prussian blue, and in the other by comparing the acid hematin color with an acid hematin standard of known iron content.

The results of our observations appear in Tables I, II, and III. The hemoglobin as determined by protein iron throughout the series is found to be slightly lower than that found by oxygen capacity. In general, however, the agreement between the two methods is excellent. We have, therefore, used the average of the three methods for comparison with the hemoglobin content of blood as found by other observers. This comparison will be seen

in Table IV. The figures of Osgood and Haskins, Wintrobe, and Haden are quoted from the article of Haden to which we have already referred. It will be noted that the figures obtained by averaging the results of these three series of observations are in more general agreement with our results than are those of any one individual series of observations. Perhaps the most important figure in the table is that termed "hemoglobin coefficient," indicating grams of hemoglobin per 100 c.c. blood when the erythrocyte count is 5,000,000 per c. mm. In regard to this figure the results of Haden are in much closer agreement with our figures than are those of Osgood and Haskins and Wintrobe.

The figure designated as "Pigment-Cell Ratio" is obtained by dividing the grams of hemoglobin per 100 c.c. blood by the millions of erythrocytes per c. mm. of blood. The figure obtained actually represents the milligrams of hemoglobin present in 100,000,000 erythrocytes. Could the precedent be established of using this figure in place of the conventional color index, it would encourage the practice of reporting hemoglobin in terms of grams per 100 c.c., and the color index, if desired, could be obtained approximately by dividing this figure by three as suggested by Cullen.<sup>2</sup> However, it seems obvious to us that the practice of reporting hemoglobin per cent and color index might well be abandoned for the reason that the normal hemoglobin value is much higher in men than in women. Calculations from an arbitrary standard are, therefore, necessary although undesirable. In the present study hemoglobin per cent was calculated from the mean of the average hemoglobin coefficients for normal men and women.

The average erythrocyte count for normal men was found to be 5.29 millions per c. mm. The average erythrocyte count for normal women was 4.62 millions.

The average hemoglobin value for men was 16.60 gm., with variations between 15.12 and 18.03 gm. For women the average hemoglobin value was 14.0 gm., ranging between 12.18 and 15.39 gm.

The average hemoglobin coefficient for men was 15.7 gm.; for women, it was 14.7 gm.

The average cell volume per cent for normal men was 46.57 per cent. For normal women it averaged 40.37 per cent. The mean of the averages of the two sexes was 43.47 per cent. The mean of the average of the two sexes per 5,000,000 erythrocyte count was 43.1 per cent.

The average saturation index of normal men was observed to be 1.017. That of normal women was likewise 1.017.

The pigment-cell ratio averaged 3.15 for the normal males and 2.95 for the normal females. The mean ratio was, therefore, 3.05. The normal limits for this figure were found to be between 2.44 and 3.51. It can be noted that a high figure was found in the two cases of pernicious anemia observed, namely, 3.67 and 3.90 and a low figure in the achromic anemias as shown by cases 72577 and 72230, namely, 2.39 and 2.34. Hence this figure can be used as well as the color index to determine the type of anemia.

## A COMPARISON OF METHODS FOR THE DETERMINATION OF URIC ACID IN HUMAN, BOVINE, AND AVIAN BLOODS\*†

GORDON H. PRITHAM, M.S., AND ARTHUR K. ANDERSON, PH.D.,  
STATE COLLEGE, PA.

NUMEROUS methods for the determination of uric acid in human blood have been developed, the chief motive being to incorporate the higher degree of accuracy of the isolation methods with the greater simplicity and ease of manipulation of the direct methods. While several of these methods have given satisfactory results on human blood, few of them have been applied to the blood of other animals. Since in this laboratory we have been especially interested in the analysis of bovine and avian (chicken) bloods, the present study was undertaken to ascertain the most satisfactory method for the determination of uric acid in these bloods.

### DISCUSSION OF DATA

In Table I data are presented to show the results of analyses of human, bovine, and avian bloods, using the Folin-Wu laked blood filtrate<sup>15</sup> and the Folin unlaked blood filtrate.<sup>12</sup> The methods of Folin<sup>11, 13</sup> of Folin as modified by Bulmer, Eagles and Hunter,<sup>5</sup> of Benedict,<sup>2</sup> and of Brown<sup>7</sup> were used with each of these filtrates, each method being applied to the filtrate directly and to the uric acid isolated as the silver salt from each filtrate. Thus twelve methods were used with each sample of blood.

The data in Table I show that in most cases the isolation methods give lower results than the direct methods. This fact is more evident in the case of laked than in the case of unlaked blood filtrates, the difference being especially pronounced in the case of laked filtrates from bovine blood. Direct and

All figures are averages of duplicate determinations.

• Five cubic centimeters of silver lactate solution were used in these cases as suggested by Bulmer, Baglos, and Hunter.<sup>5</sup>

isolation procedures agree more closely on unlaked than on laked filtrates. All isolation procedures give results which agree fairly well.

With regard to the great differences in uric acid values obtained by the direct and isolation procedures on bovine blood, the work of Benedict and his coworkers<sup>9, 10, 17</sup> should be mentioned. They have isolated from the erythrocytes of bovine blood a combined form of uric acid which is not precipitated by silver-magnesia mixture. The low values obtained with the isolation method and with the direct methods on unlaked filtrates from bovine blood might be explained on this basis, since combined uric acid would not be precipitated by the silver lactate in the isolation procedure and, being in the corpuscles, would not be present in unlaked blood filtrates.

Bulmer, Eagles, and Hunter<sup>8, 16</sup> ascribed the discrepancy between the direct and isolation methods to a substance "X" which they isolated from animal bloods, including bovine blood, and which they called a simple pyrimidine nucleoside. This compound is precipitated by silver lactate but is not liberated by acid sodium chloride, so that it would not appear in the isolation procedure.

Almost simultaneously, Benedict and his coworkers<sup>1, 3, 4</sup> isolated from pig and human bloods an interfering substance "thiasine" or thioneine, as it was later called. They claimed that this compound is not the same as substance "X," and that it causes high values in the direct method.

From the averages given in Table I it appears that for human blood Benedict's direct method applied to Folin's unlaked blood filtrate gives results more closely agreeing with the isolation procedure than any of the other methods. In the case of bovine blood, Folin's direct method applied to an unlaked blood filtrate gives results agreeing most closely with the isolation procedure. In the case of avian blood, the agreement between the direct and isolation procedures on an unlaked filtrate is about the same for Folin's as for Benedict's method.

Brown's method, with one exception, gives higher results on human and avian bloods than the other methods. In the case of bovine blood, there was no color produced when Brown's isolation procedure was applied to the unlaked filtrate. When Brown's direct method was applied to a laked blood filtrate, the results were lower than the direct methods of Folin and of Benedict.

In 1931 Benedict<sup>5</sup> suggested the use of tungstomolybdic acid for the preparation of laked blood filtrates. He<sup>6</sup> also suggested a modification of the isolation procedure. In Table II Benedict's laked blood filtrate is compared with Folin's laked and unlaked filtrates from human, bovine, and avian bloods. Folin's direct<sup>13</sup> and isolation<sup>8</sup> methods are applied to all three filtrates, and Benedict's direct<sup>2</sup> and new isolation<sup>6</sup> procedures are used on Benedict's laked filtrates.

From the averages in Table II it appears that in the case of human blood results by all the isolation methods agree closely. Of the direct methods that of Folin, used with his unlaked filtrate, gives results which agree most closely with the results obtained by the isolation procedure. It should be noted, however, that in Table I, with an unlaked filtrate, results by Benedict's direct method agreed more closely with the isolation procedure than did Folin's.

TABLE II

SHOWING A COMPARISON OF THE URIC ACID CONTENT OF HUMAN, BOVINE, AND AVIAN BLOODS BY THE DIRECT AND ISOLATION METHODS OF FOLIN AND BENEDICT ON UNLAKED AND TWO TYPES OF LAKED BLOOD FILTRATES

| SPLE. NO. | LAKED-FOLIN                         |            | LAKED-BLOOD-BENEDICT |      |        |            | UNLAKED-FOLIN |            |
|-----------|-------------------------------------|------------|----------------------|------|--------|------------|---------------|------------|
|           | FOLIN                               |            | BENEDICT             |      | FOLIN  |            | FOLIN         |            |
|           | DIRECT                              | ISOLATION* | DIRECT               | NEW  | DIRECT | ISOLATION* | DIRECT        | ISOLATION* |
| HUMAN     | MG. URIC ACID PER 100 C.C. OF BLOOD |            |                      |      |        |            |               |            |

| Average   | 3.27                                | 2.28       | 4.55                 | 2.81 | 3.53   | 2.30       | 2.51          | 2.27       |

All figures are averages of duplicate determinations.

\*Five cubic centimeters of silver lactate solution were used in these cases as suggested by Bulmer, Eagles, and Hunter.\*

With bovine blood results by the isolation method do not agree so closely as they do with human blood. Benedict's new method gives the highest values, while Folin's method, applied to his unlaked filtrate, gives the lowest values. In Table I Benedict's isolation procedure applied to Folin's unlaked blood filtrate gives lower results than Folin's isolation procedure.

In the case of avian blood, Benedict's new method gives higher results than any of the other procedures. Folin's method with his unlaked filtrate gives the closest agreement between direct and isolation procedures although in Table I the agreement is nearly as close when Benedict's procedure is used with Folin's unlaked filtrate.

In conclusion, it may be stated that for human and avian bloods, it makes little difference which method is used, provided an isolation procedure is followed. Of the direct methods those of Benedict and of Folin, with Folin's unlaked filtrate, give results agreeing closely with the isolation procedures. For bovine blood Folin's direct method, applied to his unlaked filtrate, agrees most closely with the isolation procedure. The authors have found Folin's method more satisfactory than Benedict's because the use of the urea-cyanide solution eliminates the formation of a troublesome precipitate which is always imminent when Benedict's method is used.

Since this paper was written, Folin<sup>14</sup> has made several revisions in his direct method and in the preparation of his uric acid reagent. While lack of time prevents the repetition of the work here presented, it is felt that Folin's latest technic should be considered in selecting a method for the determination of uric acid in animal bloods.

#### BLOOD IODINE STUDIES\*

##### III. A SIMPLE RESERVOIR BURET FOR MAKING MICROTITRATIONS

FRANCIS J. PHILLIPS, AND GEORGE M. CURTIS, COLUMBUS, OHIO

THE quantitative determination of the minute amount of iodine normally present in the blood and urine requires special precision apparatus. In developing an adequate method it became necessary for Davis<sup>1</sup> to construct a suitable microburet for making the titrations. This was a modification of the original reservoir buret designed by Professor F. C. Koch of the Department of Physiological Chemistry of the University of Chicago. Koch's buret was

\*From the Department of Medical and Surgical Research, Ohio State University.  
Received for publication, July 31, 1933.

adequate for making the usual microtitrations. It was a decided improvement over the old style of buret in common use.

The titration of the minute amount of iodine present in 10 c.c. of blood, however, required even a more precise buret. It became necessary to employ one accurately graduated to thousandths of a cubic centimeter. We are describing and figuring the simple reservoir buret, Fig. 1, which has finally been developed as a result of this need. This has given satisfaction in the routine daily determinations of the minute amounts of iodine normally present in the blood and urine.

A Kahn 0.2 c.c. graduated pipette was fused to the open end of the tube on the one-stem side of a three-way microbore stopcock. On the two-stem

Fig. 1.

side of the three-way stopcock, one tube is drawn to a fine capillary bore and cut 18 cm. from the stopcock, Fig. 1. This length is necessary for titration convenience. The other tube on the two-stem side of the stopcock is bent in a "J" shape. The open end is drawn parallel to the 0.2 c.c. pipette, and about 2 cm. behind it. One centimeter above the level of the zero mark on the 0.2 c.c. pipette a 10 c.c. cylinder-shaped reservoir is fused to the open end of the "J" tube. The accompanying figure of the buret used in this laboratory should be adequate as a design for any competent glass blower to follow in making this apparatus.

The buret described above has been in use in the iodine laboratory for several months. The titrations in the routine daily work here require the measurement of 0.002 c.c. increments of a 0.001 normal sodium thiosulphate

solution. With the above described buret these measurements have been accurately and conveniently carried out.

### CAGE FOR MICE AND RATS\*

ALLAN W. BLAIR, AND EMMETT B. CARMICHAEL, UNIVERSITY, ALA.

---

THIS type of cage has been used by us for the past two years, and we feel that it possesses distinct advantages over other types of cages used heretofore. In our experience some of these advantages consist in the prevention of food and bedding pollution by the segregation of each in a different compartment, the ease and cheapness of construction, the greater accessibility of the animals, the ease of cleaning, the ease of observation of the undisturbed animal and the ease of transportation from place to place. The cage serves well for feeding experiments, breeding purposes, stock animals, and general experimental purposes. It is compact, economical of space, and may be placed on a narrow shelf. Waste cotton is employed for bedding and it is placed in the upper compartment. If so desired, the food may be placed in the upper rather than the lower compartment.

*Dimensions.*—11.25 x 8.5 inches.

*Materials.*—Galvanized hardware cloth ( $\frac{1}{4}$  inch mesh) for body, door, removable floor, and as a guard around opening between the two compartments (to prevent bedding material from falling through into lower compartment); sheet zinc ( $\frac{1}{32}$  inch) for floor of upper compartment, card holder, and to form margin of door opening; sheet metal ( $\frac{1}{16}$  inch) for band at bottom of cage and door catch; heavy wire soldered to edge of mesh door (to provide additional strength and support); water container (6 inch test tube, single hole rubber stopper, glass tubing) fastened by detachable clips to side of body; enamel pan.

# MAINTAINING WATER AND AIR BALANCE DURING PROLONGED INCUBATION\*

## EXPERIENCES GAINED FROM GROWING TUBERCLE BACILLI.

H. J. CORPER, M.D., PH.D., AND MAURICE L. COHN, PH.D., DENVER, COLO.

DURING the course of years of experience, one frequently stops to glance back and smile at the arbitrariness of formed habits and empiricism which proved exceedingly wasteful of time and material and which condition could easily have been remedied by opportunity for a few moments of proper experimentation and test. Of course, the apology might be offered that the majority

Fig. 1.—The result of capping with cellophane or tin foil one week after incubation at 37° C. upon potato cylinder and inspissated egg yolk medium. Tubes 1 to 3 are the potato medium and Tubes 4 to 6 the egg medium. Tubes 1 and 4 were capped with cellophane over a cotton plug, the cellophane cap over Tubes 2 and 5 was perforated with pin holes and Tubes 3 and 6 were capped with tin foil over a paraffined cotton plug. Note the drying of the top of the medium in the cellophane capped Tubes 1, 2, 4, and 5.

of us have been trained to follow instructions implicitly and not question our textbooks or teachers. In growing tubercle bacilli the technical phases are strikingly different, and it was a stroke of "genius" that led Koch to discover the tubercle bacillus, or rather let us say correctly, in place of genius, his patience and perseverance. It is now fifty years since this discovery was made

\*From the Research Department, National Jewish Hospital at Denver.  
Received for publication, August 12, 1933.

and bacteriologists in general have failed to recognize fully the technical obstacles encountered in growing tubercle bacilli. Aside from the composition of the medium which has been elaborately studied by us,<sup>1, 2, 3</sup> there are two factors dependent upon technical detail that may spell success or failure in growing these bacilli, the maintenance of the water and air balance. To attempt to maintain the water balance of the medium by any means of supplying water in the incubator or in the cans containing the culture tubes or flasks is obviously futile as only experience will prove, or possibly a little reflection upon mother's bread box, or the storekeeper's unceasing vigil to

Fig. 2.—The same tubes shown in Fig. 1, after three weeks at 37° C. Note the marked drying of the mediums in Tubes 1, 2, 4, and 5 (cellophane capped) and the evaporation of the condensation water in the bottom of the tubes.

prevent mold disasters, will provide the evidence. And molds extend into the smallest crevices, even through the bacteriologic impervious cotton plug if given time and moisture. Dryness is the enemy of mold and, therefore, it is better to maintain water balance by preventing evaporation; and yet one may ask how to maintain air balance and still prevent evaporation in a dry incubator, particularly in a dry climate of extremely low humidity and over a long period of time. The investigator soon learns that explanations must await facts, and so the experiences to be recorded will be presented as facts which anyone can easily explain on the basis of present knowledge.

It has been the custom of the senior author over many years in growing tubercle bacilli to utilize the method of impregnating cotton plugs or culture tubes with hot paraffin, and then covering the tubes with tin foil or cloth impregnated with paraffin, with the cap secured by a small rubber band to prevent drying of the medium. In practice this method had met the needs apparently satisfactorily, when a trial of cellophane capping was advocated to us as being more easily used and readily applied to the tubes or flasks. The objection raised by us to the use of cellophane was based on our knowledge of the water and moisture permeability of this material, and especially

Fig. 3.—A comparison of capping with tin foil or paraffined cloth. Tubes 1, 2, and 3 are inspissated egg yolk medium, Tubes 4, 5, and 6 potato cylinder medium. Tubes 1 and 4 are controls plugged with paraffined cotton. Tubes 2 and 5 are in addition capped with tin foil and Tubes 3 and 6 are capped with paraffined cloth. Note the greater drying of the medium and condensation water in Tubes 1 and 4 uncapped, and the better maintenance of water balance in the paraffin cloth capped Tubes 3 and 6 as compared to the tin foil capped Tubes 2 and 5 after four weeks at 37° C.

because one of us has had intimate knowledge of its use for preevaporation. Those advocating the use of cellophane capping maintained it would save labor and obviate the use of the rubber band as well as paraffining of the cotton plug, and, of course, would make easier the access of air (an erroneous deduction). It was tried with the results shown in Figs. 1 and 2. In commenting on this test it may be noted that very little difference in the rate of drying of the medium occurred regardless of whether the cellophane had been perforated or not.

There are a number of methods which have been variously advocated for maintaining the water balance in culture tubes over relatively long periods of time of incubation, and two of them were cited above, the tin foil capping or paraffin cloth capping, but we are not aware of actual tests recorded in the literature of the relative merits of these two. To us they appeared equally efficient and the tin foil, although more costly, possessed the advantage of being less messy and less bulky. Test, however, proved the paraffin cloth to be more efficient as shown in Fig. 3. In some laboratories it is the

Fig. 4.—A comparison of capping with cork stoppers and tin foil or paraffin cloth after keeping inspissated egg yolk medium for four weeks at 37° C. Note the absence of drying in the tubes stoppered with the plain nonparaffined cork (Tube 3) and with the paraffined cork (Tube 1) as well as with the paraffin cloth cap while Tube 2 tin foil capped showed evidences of drying of the upper portion of this medium at this time.

custom to merely pour a layer of hot paraffin over the cotton plug without attempting to impregnate all the fibers, and then to perforate the paraffin plug with a few pin holes. This method is fairly satisfactory but fails to remove entirely the water absorbing powers of the cotton plug, and each time that the tube is to be opened the plug of paraffin must be removed, which in our hands has proved less satisfactory than other methods, including the paraffin cloth which with the paraffin impregnated cotton plug is more efficient for preventing water evaporation.

Recently one of us<sup>4</sup> described a tissue substrate method for practice, and for simplicity recommended the use of a lightly paraffined cork. It seemed advisable, therefore, to determine the merit of the cork for the purpose of maintaining water and air balance in culture tubes. The maintenance of water balance by the cork placed over the paraffin impregnated cotton plug is well illustrated in Fig. 4.

However, this experiment proved only the adequacy of the cork for maintaining water balance, and our knowledge regarding the use of the cork

Fig. 5.—The results of capping with tin foil, with the cork stopper (not paraffined) and a paraffined cork stopper upon the growth of small numbers of tubercle bacilli (a human strain) on an inspissated egg yolk medium after three months' incubation at 37° C. All the cotton plugs were impregnated with hot paraffin, and Tubes 1 and 2 were capped with tin foil, Tubes 3 and 4 were stoppered with a plain dry cork, and Tubes 5 and 6 with a paraffined cork inserted fairly tightly. Note that the growth of the bacilli in the plain corked Tubes (3 and 4) is equal to that in the tin foil capped tubes (1 and 2) in both the 0.000,1 mg. plantings (Tubes 1 and 3) and in the 0.000,001 mg. plantings (Tubes 2 and 4), while in both plantings the growth was retarded in the tubes stoppered with the paraffined corks (Tubes 5 and 6). The latter finding is readily understood on the basis of the relative imperviousness of the paraffined cork to air especially when tightly inserted into the tube.

as a stopper for effervescing and fermenting beverages made us doubt its value in maintaining air balance. Manometric tests assured us that the dry cork was readily pervious to air, but that the cork heavily impregnated with paraffin and tightly inserted into a tube was almost completely impervious to air and was, therefore, unsuited to our use for growing tubercle bacilli.

as a stopper for effervescing and fermenting beverages made us doubt its value in maintaining air balance. Manometric tests assured us that the dry cork was readily pervious to air, but that the cork heavily impregnated with paraffin and tightly inserted into a tube was almost completely impervious to air and was, therefore, unsuited to our use for growing tubercle bacilli.

If the cork was only lightly impregnated with paraffin and was only loosely inserted into the tube, it would not prevent air access in sufficient amount for growing tubercle bacilli. It is well also to remember that the water wet cork is far less pervious to air than the dry cork. To further test the value of the dry cork, it was given a thorough trial in culture tests with tubercle bacilli in graded seedings (see Fig. 5), and proved sufficiently valuable both from an economic and efficiency standpoint so that it is now used in all our culture tube work in place of tin foil or paraffin cloth, being inserted above the cotton plug which has been impregnated completely but lightly with hot paraffin. The corks can be repeatedly used and can be freed from paraffin, if desired, by washing in gasoline or some other readily volatile paraffin solvent, after which they may be air dried and, finally, to free from traces of the solvent, may be placed in the dry sterilizer for an hour or two.

The efficiency of the paraffining procedure in maintaining water and air balance in culture flasks is well illustrated by a report just presented by us<sup>7</sup> in which we found that tubercle bacilli remained viable for over twelve years after growing in nursing bottles containing broth, stoppered with a paraffined cotton plug, and covered with paraffined cloth. Some of these bottles lost as little as one-quarter to one-half ounce of liquid out of an original three ounces placed in the flask twelve years previously.

In conclusion, it may be stated that the problem of maintaining water and air balance in culture tubes and culture receptacles appears to be one of preventing the conduction of moisture from these receptacles by avoiding the use of moisture absorbent materials, or by satisfactorily impregnating these with a completely nonabsorbent and water impervious material, such as paraffin. It also appears that this can be attained without appreciable influence upon adequate gaseous exchange, especially sufficient to maintain conditions required for the multiplication of slow growing microorganisms, such as the tubercle bacillus.

# DEPARTMENT OF REVIEWS AND ABSTRACTS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

**LIVER, Silver Nitrate Reaction and Its Applicability to the Diagnosis of Diseases of,**  
Rosa, L. Wien. Klin. Wchnschr. 46: 1104, 1933.

Rosa describes the test below as of value in the diagnosis of hepatic diseases.

Set up 5 test tubes and introduce the following amounts of urine: 1, 2, 1.5, 2, and 5 c.c. Then add the following amounts of 10 per cent solution of silver nitrate: 0.2, 0.2, 0.1, 0.1, and 0.1 c.c. The resultant dilutions are thus 1:5, 1:10, 1:15, 1:20, and 1:50. While frequently shaking boil the tubes for from thirty to forty seconds in a water-bath. Remove from the bath and allow the precipitate to settle.

Negative reaction: sediment, snow white; supernatant fluid transparent yellow.

Positive reaction: lilac, brown, or black precipitate with supernatant fluid of same color.

The more severe the pathologic process, the higher the dilution in which the reaction occurs.

The reaction is related to the sodium chloride concentration of the urine.

**TUBERCULOSIS, Vernes Flocculation Test in,** Murray, R. South African M. J. 7: 645, 1933.

From a study of 121 cases Murray concludes that the sedimentation rate and the Vernes test do not appear to be related in any simple manner.

In definitely diagnosed cases of tuberculosis the Vernes test would not appear to be invariably positive, there being negative results in some 6.4 per cent of cases.

In cases where recovery is taking place, the sedimentation test appears to give a normal reading sooner than the Vernes test.

**MILK, Preservation of for Streptococcus and Abortus Examination,** Bryan, C. S. Am. J. Pub. Health 23: 1182, 1933.

A 1:10,000 concentration of brilliant green (0.1 c.c. of 1 per cent aqueous solution to 10 c.c. of milk) was found highly satisfactory.

**MALARIA, Vital Staining of Mitochondria in,** Boucher, H. Compt. rend. Soc. de biol. 112: 882, 1933.

Mitochondria can be demonstrated in the malaria parasite *Plasmodium vivax* by vital staining with Janus green.

The stain is prepared as follows: Of a saturated solution in absolute alcohol of neutral red 0.4 c.c. is added to 10 c.c. of absolute alcohol to which is added also three drops of a saturated alcoholic solution of Janus green. A drop of this is allowed to dry on a perfectly clean slide and the moist blood preparation is made on the thin film of stain. The mitochondria in the form of spherical granules stained by the Janus green half a micron in diameter vary in number from 1 to 20 according to the size of the parasite. The neutral red stains granules in the red blood corpuscles, the rose coloration assumed by the cytoplasm of the parasite being due to a reduction product of the Janus green.

**BLOOD CHOLESTEROL, In Chronic Nephritis and Retention Uremia, Ashe, B. I., and Bruger, M. Am. J. M. Sc. 186: 670, 1933.**

In cases of chronic Bright's disease with marked nitrogen retention, a low plasma cholesterol foretells death in uremia. In most cases this low reading is observed at an appreciable interval before death; in rare cases such a level is found only about twenty-four to forty-eight hours before exitus.

An elevated plasma cholesterol indicates a good prognosis as to recovery from pre-uremic symptoms but does not preclude the possibility of death from causes other than uremia.

There appears to be no close relation between the height of the plasma cholesterol and the degree of edema in patients with chronic Bright's disease.

There is some clinical evidence of a reciprocal relation between the blood urea and the plasma cholesterol; at other times this relation is offset by other factors. A constant inverse relation between the plasma proteins and cholesterol was not observed.

The diminished cholesterol content of the plasma observed in cases of Bright's disease dying of retention uremia is probably due to such contributing factors as cachexia and anemia.

**FIBRINOGEN, Quantitative Determination of in the Blood, Boehm, G. Diagn. E. Techn. di Lab. 4: 683, 1933.**

The author describes a simple technic as follows:

1. Fill and empty a sterile 10 c.c. glass syringe with 20 per cent potassium oxalate, thus leaving a thin film in the syringe.

2. Withdraw from 6 to 7 c.c. of blood by venipuncture, place in a test tube and centrifuge.

3. Remove 1 c.c. of plasma and dilute with 9 c.c. of 0.85 per cent saline and from this 1:10 dilution prepare a 1:100 dilution.

4. To a series of 16 tubes from 8 to 10 mm. in diameter add plasma and saline as shown in the table below:

| TUBE | PLASMA C.C.   | SALINE C.C. | CONCENTRATION OF PLASMA |
|------|---------------|-------------|-------------------------|
| 1    | 1.0 of 1: 10  | 0           | 1.0                     |
| 2    | 0.7 of 1: 10  | 0.3         | 0.07                    |
| 3    | 0.5 of 1: 10  | 0.5         | 0.05                    |
| 4    | 0.4 of 1: 10  | 0.6         | 0.04                    |
| 5    | 0.35 of 1: 10 | 0.65        | 0.035                   |
| 6    | 0.3 of 1: 10  | 0.7         | 0.03                    |
| 7    | 0.25 of 1: 10 | 0.75        | 0.025                   |
| 8    | 0.2 of 1: 10  | 0.8         | 0.2                     |
| 9    | 0.15 of 1: 10 | 0.85        | 0.015                   |
| 10   | 1.0 of 1:100  | 0           | 0.01                    |
| 11   | 0.9 of 1:100  | 0.1         | 0.009                   |
| 12   | 0.8 of 1:100  | 0.2         | 0.008                   |
| 13   | 0.7 of 1:100  | 0.3         | 0.007                   |
| 14   | 0.6 of 1:100  | 0.4         | 0.006                   |
| 15   | 0.55 of 1:100 | 0.45        | 0.0055                  |
| 16   | 0.5 of 1:100  | 0.5         | 0.005                   |

5. To each tube add 1 drop of 10 per cent calcium chloride solution and allow to stand in the ice box for thirty minutes.

6. Read for (a) the dilution showing a definite turbidity and (b) the dilution showing complete coagulation when the tube is inclined.

The amount of fibrinogen is determined by the formula:

(Unit) of fibrinogen. (U.Fg.) =  $\frac{1}{p}$  where p equals the amount of plasma in the tube (as shown in the table).

The author gives the normal as 40 or 60 U.Fg. per 1 c.c. of plasma.

**SYPHILIS, The Value of the Sachs-Witebsky Reaction (Citochol) for the Diagnosis of,**  
 Sebastion, F. *Diagn. E. Techn. di Lab.* 4: 641, 1933.

The author reports favorably upon this test which he believes to be specific, sensitive, and easy to read.

His technic follows: To 0.2 c.c. of serum inactivated at 55° C. for thirty minutes add 0.1 c.c. of 1:3 Citochol-saline mixture which has been allowed to ripen for thirty minutes at room temperature.

After twenty minutes add 1 c.c. of 0.85 per cent saline solution and shake. Readings are made after one hour, positive reactions being indicated by flocculation, the mixture remaining clear and limpid in a negative reaction.

**ANEMIA, Production of Erythrocytes, Reticulocytes, and Hemoglobin in,** Murphy, W. P.  
*Arch. Int. Med.* 52: 829, 1933.

It is well known that the magnitude, and to some extent the rate, of the response of the reticulocytes to therapy is in part dependent on the method of staining and technic of counting the reticulocytes, the number of erythrocytes present when treatment is started and the state of health of the patients in certain respects other than the anemia.

If the various secondary factors which influence the rise in reticulocytes are assumed to be constant, the magnitude of the response of the reticulocytes will indicate the potency of the material used if it is administered in submaximal amounts. The data presented, particularly for patients treated with maximal amounts of potent material, as with a concentrated solution of liver extract administered intramuscularly, indicate that a reticulocyte response of equal magnitude may be observed following the use of varying amounts of equally potent material, that the response will occur more quickly following the initial administration of large amounts, that the magnitude of the increase in erythrocytes may not vary directly with the magnitude and duration of the rise in reticulocytes and that the rate of increase of the erythrocytes is a more accurate indication of the effectiveness and potency of substances used in the treatment of patients with pernicious anemia than is the rate and magnitude of the reticulocyte response.

The explanation for the lack of correlation between increases in reticulocytes and erythrocytes as observed following treatment with various substances is not obvious and is probably not entirely controlled by the condition of the blood-forming organs at the time treatment is started. The variation in response to treatment by different means may be dependent on the rate of absorption or the utilization of the active principle under the various methods of its administration. If this is the case, it is probable that when administered in large amounts, as by intramuscular injection, the active material presented ready for the immediate use of the blood-forming organs causes more rapid maturation of the erythrocytes, so that the proportion of mature to immature cells (reticulocytes) in the circulation is greater than when less of the potent substance is available.

Is it possible, however, that two factors are present in the various materials used in the treatment for pernicious anemia, a stimulating (or reticulocyte-producing) and a maturing (or erythrocyte-producing) one? These may occur in varying proportions in different materials which have been used, the maturing occurring in greater proportion in the more refined and concentrated liver extract for intramuscular use.

In the treatment of the patient whose blood is in a state of relapse, it is desirable that improvement of this condition be promoted as rapidly as possible. Observations indicating an unusually rapid increase in erythrocytes following the intramuscular injection of initial large amounts of a concentrated solution of liver extract (12 c.c. prepared from 400 gm. of liver) and followed by infrequent smaller injections are presented. That this material is of a high degree of potency and that treatment by this means insures optimal efficacy are well illustrated by the improvement shown.

The administration of large doses of iron during treatment with liver extract parenterally is strongly recommended. By this means one may be more certain to obtain the maximum

effect of the liver material by preventing the development of deficiency in iron as a result of the rapid maturation of erythrocytes produced by the parenteral method of therapy.

**RHEUMATIC FEVER, Intravenous Vaccination With Streptococci, Wilson, M. G., Josephi, M. G., and Long, D. M.** Am. J. Dis. Child. 46: 1330, 1933.

The curves of the seasonal incidence of recurrence of rheumatic fever for subjects receiving hemolytic streptococcus vaccine therapy in 1928 and 1929 show a definite upward trend in 1931 as compared with the control group.

Twenty-three (19 per cent) of the treated subjects as compared with 15 (17 per cent) of the controls remained free from evidence of rheumatic activity for the three-year period of observation.

The annual incidence of recurrence for subjects receiving hemolytic streptococcus vaccine therapy was 48 per cent for 1929, 39 per cent for 1930 and 37 per cent for 1931.

The subjects who received a second course of treatment with hemolytic streptococcus vaccine in 1929 exhibited more recurrences in 1930 than subjects receiving only a single course of treatment.

The first series of 26 children who received typhoid vaccine intravenously in the fall of 1930 shows a diminished incidence of recurrence comparable to that observed following hemolytic streptococcus vaccine in the previous investigation.

The incidence of recurrence following streptococcus vaccine (polyvalent streptococcus B E and *Streptococcus viridans*, autogenous, individual and pooled) did not seem to be influenced by treatment.

There was no significant difference in the incidence of recurrence or manifestations of activity following intravenous therapy with various antigens.

The results secured in this investigation would seem to support the view that the temporary diminished incidence of recurrence observed to follow intravenous treatment with hemolytic streptococcus vaccine in the previous investigation was probably unrelated to therapy.

Intravenous vaccination with various antigens in the dosage used did not seem to influence the incidence of recurrence of rheumatic activity in the children studied.

**THYROID DYSFUNCTION, Gastric Acidity in, Wilkinson, S. A.** J. A. M. A. 101: 2097, 1933.

Of 100 cases of hyperthyroidism, 36 per cent showed achlorhydria, and the average acid of all cases was reduced to slightly more than half the normal.

The observation is made that the incidence of achlorhydria in hyperthyroidism rises in proportion to the duration of the toxicity rather than the degree of the toxicity.

After thyroidectomy, only 10.5 per cent show achlorhydria. The average free acid is raised to about the normal value for the entire series.

A theory is offered that the depression of gastric acidity is a phenomenon of extreme sympathetic overstimulation.

Hypothyroidism, in this series at least, produces a definite tendency to hyperacidity.

**ANEMIA, Chronic Idiopathic Hypochromic, Mettler, S. R., Kellogg, F., and Rinehart, J. F.** Am. J. M. Sc. 186: 694, 1933.

Data are presented of studies made on the relationship of diet and nutrition to anemia in 10 cases of chronic idiopathic hypochromic anemia associated with hypochlorhydria or achlorhydria and defective diet.

The response of the bone marrow, as determined by the hemoglobin and production of erythrocytes, to iron administered in large daily oral doses in the form of iron and ammonium citrate (U.S.P.) was compared to the response in patients on an "iron rich" diet. In addition, a comparison was made of the response of the bone marrow to a diet rich in iron and to a meal previously digested in vitro with hydrochloric acid and commercial pepsin.

The bone marrow responded rapidly and excellently to large doses of inorganic iron, but there was no evidence of increased hematopoiesis after the ingestion of an "iron rich" diet for a long period of time. There was, however, a rapid and satisfactory increase in concentration of hemoglobin, production of red cells, and a slight reticulocyte response following the administration of predigested meals.

It is concluded, from these studies, that chronic idiopathic hypochromic anemia is one presumably due to a deficiency of iron wherein gastric dysfunction leads to failure in utilization of organic (dietary) iron.

**EOSINOPHILIA, Induction of in Normal Animals, Banerji, N.** *Am. J. M. Sc.* 186: 639, 1933.

An elevation in the relative number of eosinophiles was induced in rabbits subjected to increased carbon dioxide tension of the blood, either by intravenous administration of carbon dioxide solutions or by exposure of the animal to an atmosphere containing increasing amounts of this gas.

From this result, it is concluded that an alteration in the acid base equilibrium of the body appears to incite an eosinophilia.

Further studies, it is hoped, will lead to a better understanding of the mechanism of this alteration.

**CANCER, The Reaction of the Arterial Blood in, Dickinson, S., and Havard, R. E.** *Brit. J. Exper. Path.* 14: 394, 1933.

The results of previous workers are summarized and discussed.

The technic is described of collection of samples of arterial blood from patients with and without malignant diseases, and the measurement of the  $P_H$  of the blood at 37° C., by two independent glass electrodes.

The results support the conclusion that the blood of patients with malignant disease of the mouth or skin, or with secondary glands, is not more alkaline than that of patients free from malignant disease.

An experiment is described that demonstrated that momentary alterations of respiration can affect the  $P_H$  of the blood.

**ENTERITIS, Polytropous (Acute Infectious Gastro-Enteritis, Spencer's Disease), Wildman, H. A.** *Arch. Int. Med.* 52: 959, 1933.

There apparently exists quite generally a clinical entity which has erroneously been called gastrointestinal influenza, food poisoning, ptomaine poisoning, biliousness, acute auto-intoxication, dietary indiscretion and the like. Considerable information concerning the etiology, epidemiology, pathogenesis, symptomatology and differential diagnosis of this condition has been gathered from observations on more than a thousand cases seen within the past seven and a half years. A distinctive name is now proposed. The present report is based on a study of about 750 college students who had from one to six or more attacks between September, 1927, and June, 1932. Much more work is needed to settle some points, particularly those concerning the etiologic agent and the pathologic condition which it produces.

**ACETANILID, Influence of Caffeine on Effects of, Higgins and McGuigan.** *J. Pharmacol. & Exper. Therap.* 48: 276, 1935.

Study upon animals of the effects of acetanilid plus caffeine did not present evidence of increased acetanilid toxicity. Mice receiving daily in their drinking water 50 per cent of the fatal hypodermic dose of acetanilid and 20 per cent of the fatal hypodermic dose of caffeine showed practically no effects from the drugs. The enormous dose with their food (0.5 per cent acetanilid and 0.5 per cent acetanilid plus 0.1 per cent caffeine or 650 mg. per

kilogram body weight) served only to delay growth in mice. Caffeine seemed only to lessen the toxicity. After six weeks the animals were placed on normal diet and rapid gain in weight followed.

Three hundred and twenty-five mg. acetanilid plus 62 mg. caffeine per kilogram per day had little or no effect on growth.

In rabbits the fatal dose of acetanilid is about 1.5 gm. per kilogram. In anesthetized dogs fatal doses cause respiration to stop before the heart. In therapeutic amounts caffeine would not add to the toxicity of acetanilid.

**SYPHILIS, Conjugal, A Statistical Study, Decker, H. B. Am. J. M. Sc. 187: 111, 1934.**

There is presented an investigation of the records of 376 families in which syphilis was present in at least one member of the conjugal union.

Sixty husbands and 98 wives were syphilitic with nonsyphilitic spouses.

In 218 families both husband and wife were syphilitic.

It is concluded that the type of syphilis depends upon the individual rather than upon any special strain of treponema.

Late syphilis is relatively noninfectious. Infectivity varies inversely with the duration of the disease.

**GRANULOMA INGUINALE, Further Studies on the Etiology of, De Monbreun, W. A., and Goodpasture, E. W. Am. J. Trop. Med. 13: 447, 1933.**

A gram-negative bacillus belonging to the aerogenes group has been isolated from the lesions of two cases of granuloma inguinale, and from the feces of two out of four other cases of the disease.

This bacillus reproduces exactly the morphological characteristics of the Donovan microorganism, including the typical Donovan body which appears as a secondary phenomenon in older cultures in blood media.

Cultures of this bacillus have failed to reproduce the specific lesions of granuloma inguinale when inoculated into lower animals and into man.

The Donovan microorganism apparently increases in mononuclear cells in tissue cultures in the primary explants from human lesions, but has failed to grow in subcultures.

Notwithstanding failure to reproduce granuloma inguinale experimentally with cultures of the bacillus described, the hypothesis that this disease is primarily a chronic intestinal infection with a member of the aerogenes group of bacilli, with secondary infection of the skin from constant fecal contamination is advanced as worthy of further investigation.

**ACTINOMYCETES, Modified Sabouraud Medium for Cultivation of Acid-Fast, Scudder, S. A. Science 79: 16, 1934.**

The following medium was found satisfactory:

Maltose, 4 per cent; Difco peptone, 1 per cent; flaked agar, 1.8 per cent; dissolved in unfiltered beef heart or veal infusion instead of water. No adjustment of reaction is necessary. If desired, glycerin and other carbohydrates may be added. The use of the medium as slants favors the development of acid-fastness in about four days. Simultaneously with the appearance of the acid-fast portions of the growth, a grayish-brown powdery substance develops upon the upper portion of the slant.

**MICROSCOPY, Using a "Dry" Microscope Objective on Uncovered Objects, Sauer, F. C. Science 78: 537, 1933.**

By attaching a cover glass temporarily to the lens (by a film of cedar oil, mineral oil, or water) the study of uncovered objects is greatly improved.

### Der Krebs, seine Entstehung und Erklärung\*

A THEORETICAL discussion which defines cancer as a biologic result of the disturbance of the three factors which regulate cell life, that is (1) a disturbance of the life forces resident in the cell, (2) a lack of normal hormonal influence or excess of pathological hormonal influence, and (3) lack of the trophic innervation of the vegetative nervous system. Disturbance of all three factors causes the revolutionary cancerous transformation of the cell; disturbance of two factors produces the precancerous stage.

### Die normale und pathologische Physiologie der Milz†

THE author modestly acknowledges the scanty and conflicting evidence concerning the functions of the spleen and states that he has spent years in personal attempts to decide certain disputed points. He hopes that his book may be of assistance to others working in this dark and difficult field. One of the anomalies is the fact that removal of the spleen in man causes no detectable symptoms while its removal in rats and many other experimental animals results in a few days in a Bartonella infection and a rapidly fatal anemia. Apparently most laboratory animals harbor a latent Bartonella infection which is normally held in check by the spleen but which runs wild after splenectomy. In the various chapters the spleen is considered as a blood reservoir, as a hematopoietic and hemolytic organ, as a protection against infections and tumors, as it influences the digestive tract and metabolism, and as an organ of internal secretion.

### Das Chlorophyll als Pharmakon‡

CHLOROPHYLL, the common green respiratory pigment of the plant world, has recently been studied intensively by Willstätter and others, and it has been found to be closely related in chemical structure to hemoglobin, the common red respiratory pigment of the animal world. The nucleus of each consists of a ring structure made up of four pyrrole groups and a metal, iron in hemoglobin and magnesium in chlorophyll. In cases of anemia it would seem a natural and logical indication to supply this pyrrole nucleus for the building of new blood. In fact, both blood and chlorophyll have been so used but the results are no better than are obtained by the administration of simple forms of iron. Bürgi, however, finds that chlorophyll has a very general tonic effect on all the organs and functions of the body; it tones the heart and blood vessels, it increases peristalsis, it lessens the fatigue of nerve muscle preparations, etc. He finds that rabbits fed green vegetables are brighter and more active, and we all know that the old cow is rejuvenated when she gets green grass in the spring. Green vegetables, however, contain also carotinoids, vitamins and other products, but Bürgi finds that extracted chlorophyll has this same tonic effect and is more completely absorbed than is chlorophyll taken in the form of green vegetables.

### The Anatomy of the Rhesus Monkey\*

CONSIDERING the extensive use of the rhesus monkey as a laboratory animal, it is strange that some such publication as this volume has not hitherto been available.

While not, strictly speaking, a textbook, the volume nevertheless represents the first comprehensive description of the anatomy of the old world monkey and as such may justly be regarded as a pioneer in this field.

It consists of eighteen chapters representing the studies of competent contributors thoroughly familiar with their subject.

Each contributes a detailed study of a definite field so that the volume as a whole covers the subject in its entirety.

It is, of course, not to be expected that the volume should approximate in character the textbooks of human anatomy because of the limited numbers of dissections and anatomical investigations upon which its studies are based.

Nevertheless, the research worker and the student of comparative anatomy will find in its pages much that has not before been subjected to extensive study or comprehensive description and while future studies may, to some extent, lead to modification or revision of this or that section or portion of a section, the work represents a contribution of great value and definite utility.

Very wisely, it seems to the reviewer, and contributing to the usefulness of the book, the B. N. A. nomenclature, rather than that of comparative anatomy, has been used throughout.

An appendix contains an excellently written and illustrated account of the housing and care of monkeys which should prove most useful.

The contributors, editors, and publishers may be congratulated upon the production of a useful volume.

---

### A System of Clinical Medicine†

THE fact that this book, addressed particularly to students and practitioners, has reached a ninth edition is *prima facie* evidence of its practical character and usefulness which becomes evident even with the most cursory perusal of its pages.

There are many books concerned with clinical medicine and the problems confronting the practitioner, all having their place and value. Few, however, will in a broad sense possess any greater utility than Savill's.

This is largely due to the somewhat different, and original plan upon which it is based in presenting the subject from the purely clinical standpoint, the bedside point of view, as it were, in which the problem confronting the physician is to correlate the symptoms observed with their underlying cause.

The discussion of each condition, therefore, is approached from the following angles:

First, a discussion of the symptoms and their possible causes in which is presented a comprehensive outline of the signs indicative of disease in the organ or region under discussion, as well as a discussion of the fallacies incident to their detection and a differential account of their various possible causes.

Second, a discussion of the physical signs in that region and the methods of eliciting them.

Third, a clinical classification of the various diseases affecting the region in question and a discussion of the various diseases arranged in accordance with their clinical relationships.

By this arrangement the reader is presented with a very useful clinical index of diseases and finds himself reading the diagnosis, prognosis, and treatment of the disease at

\*The Anatomy of the Rhesus Monkey. Edited by Carl G. Hartman and William L. Straus Jr. Cloth, 122 figures. The Williams & Wilkins Co., Baltimore, Md.

†A System of Clinical Medicine. By Thomas Dixon Savill, M.D. Ninth edition, cloth, pp. 1063, 163 illustrations, 6 colored plates. William Wood and Co., Baltimore, Md.

hand and also, in immediate proximity finds a description of conditions which clinically and pathologically often more or less resemble it and thus may be mistaken for it.

For any degree of success the carrying out of such a plan necessarily requires a foundation of broad and digested experience. That Dr. Savill has been successful in his project the volume itself bears witness.

The present edition, thoroughly revised and brought up to date, brings to the practitioner and student an exceedingly useful and well-written presentation.

### Food-Borne Infections and Intoxications\*

WHILE food poisonings and food infections are relatively unimportant as a cause of death, a sufficient number of outbreaks occur to warrant an understanding of their nature and mechanism.

In this book, a companion volume to the author's previous text upon *The Microbiology of Foods*, food infections and food intoxications are presented in a thoroughly comprehensive and satisfactory manner.

Those interested in this subject will find in this book practically the information available concerning every type of food infection or poisoning on record. Under each heading will be found illustrative case reports and records of outbreaks, the bibliography being exceptionally full and complete. The style is clear, simple, and eminently understandable.

This book and its companion should be of interest, not only to the physician who may be confronted with outbreaks of this character as well as with others simulating food poisoning but really something else, but especially to health officers and laboratory workers who may be called upon to study such outbreaks.

It can be recommended as a thorough and comprehensive study of a subject not always clearly understood.

### Textbook of Pathology†

THIS well-known book requires no introduction, having served as a standard text for the last decade.

In this, the third edition, will be found a number of changes and additions, not only in the text, some portions of which have been entirely rewritten, but also as concerns the illustrations, a number of which are new and all of which in general will be found adequate.

While following in general the common division of the subject into General and Special Pathology, this distinction has not been overemphasized. Based upon the author's experience as a pathologist and teacher, the volume will be found practical and of value, not only to the students to whom it is particularly addressed, but also to the clinician and, as heretofore, as a work of reference.

There is an adequate index.

### Die Spezifität der serologischen Reaktionen‡

THIS is an attempt to bring together, coordinate, and interpret for German readers the results of his own investigations and those of his coworkers and to discuss the very difficult problems of biological specificity, especially from the chemical standpoint. He takes up in order the specificity of proteins, of cell antigens and antibodies; then the specificity of serological reactions with artificial complex antigens and finally the specific cellular substances such as the specific carbohydrates and lipids. It has copious references and an index.

state and who maintained that state through 1932. The rate was even higher than that for the "chronically poor" group, those who were poverty stricken in 1929 and 1932.

The rate of disabling illness in families of the unemployed was 25 per cent higher than that in families containing part-time workers and 39 per cent higher than that among families of full-time wage earners.

These conclusions are such as one would anticipate, and could easily form the basis for generalizations regarding the effect of a financial depression on sickness in general. The authors, however, very wisely emphasize that conclusions should be drawn only on the material studied. They make no attempt to draw broad implications and caution the reader to exercise similar restraint. The group is relatively small and does not necessarily represent a cross-section for the United States. They also point out that specific interpretation of increased illness rate in terms of impaired vitality cannot be made without knowledge of the nature of the illnesses experienced.

In this study the results were what one would expect. In another recent analysis<sup>2</sup> they were the reverse. Deaths from tuberculosis in 28 states surveyed were lower in 1932 than in any of the preceding four years. The fall in rate has followed the regular established curve for tuberculosis, apparently uninfluenced by the depression. The rate per 100,000 in 1928 was 77.3; in 1932, 60.4.

A very interesting example of the difficulty of drawing statistical conclusions from relatively small figures is reported by C. M. Smith in his study of housing conditions and respiratory disease in Glasgow.<sup>3</sup> This also was in a measure an economic survey. The prevalence of respiratory disease was studied in two Glasgow areas, one a poor-class quarter, a slum district, and the other a rehousing area. The latter corresponds to our model tenement developments. The survey covered an entire year. The inhabitants of the two areas, numbering about 1,000 each, were in comparable economic states, but the housing facilities in one group were presumably much more sanitary than in the other.

To our surprise we find that there was a greater morbidity from acute respiratory disorders in the rehousing area than in the slum quarter. Here we are presented with an apparent paradox to the anticipated, and the explanations presented are based upon isolated observations rather than figures. Smith states that the results cannot be taken as evidence that improved housing conditions have been without effect on the prevalence of respiratory disease for the following reasons. In the slum district 20 per cent of the population were foreigners, chiefly Jews and Lithuanians, among whom there was less unemployment and dietary habits were better than in the rest of the population. The willingness of informants to report cases is a factor, and the author believes that reporting of illness was more accurate in the model tenement group. Theoretically, provision in the model tenement district allowed for fewer persons per room, there being only about one-fifth as much overcrowding. As a matter of fact a large proportion of the rehoused population, not long removed from the slums, continued to use just one of their several rooms for sleeping, especially in cold weather. Therefore, during the night, crowding was just as prevalent

### The Hazards of Statistical Interpretation

A SURVEY of the effect of the economic depression upon sickness has been undertaken by Perrott, Collins and Sydenstricker.<sup>1</sup> The completed analysis will be based upon the records of illness in 1933 as compared with the economic history from 1929 to 1932, in more than 12,000 families in eight large cities, a group of coal mining communities, and a group of cotton mill villages. The authors' preliminary report presents the preliminary results in three of the large cities, Birmingham, Detroit, and Pittsburgh. This comprises a group of 2,566 families, 11,330 individuals. They find a definitely higher incidence of disabling illness among individuals in the lower income classes than among those with higher incomes. The highest sickness rate is reported in the group which in 1929 had been in reasonably comfortable circumstances but which in 1932 had dropped to relative poverty. The sickness rate in this group is 60 per cent higher than among those who in 1929 were in comfortable economic

state and who maintained that state through 1932. The rate was even higher than that for the "chronically poor" group, those who were poverty stricken in 1929 and 1932.

The rate of disabling illness in families of the unemployed was 25 per cent higher than that in families containing part-time workers and 39 per cent higher than that among families of full-time wage earners.

These conclusions are such as one would anticipate, and could easily form the basis for generalizations regarding the effect of a financial depression on sickness in general. The authors, however, very wisely emphasize that conclusions should be drawn only on the material studied. They make no attempt to draw broad implications and caution the reader to exercise similar restraint. The group is relatively small and does not necessarily represent a cross-section for the United States. They also point out that specific interpretation of increased illness rate in terms of impaired vitality cannot be made without knowledge of the nature of the illnesses experienced.

In this study the results were what one would expect. In another recent analysis<sup>2</sup> they were the reverse. Deaths from tuberculosis in 28 states surveyed were lower in 1932 than in any of the preceding four years. The fall in rate has followed the regular established curve for tuberculosis, apparently uninfluenced by the depression. The rate per 100,000 in 1928 was 77.3; in 1932, 60.4.

A very interesting example of the difficulty of drawing statistical conclusions from relatively small figures is reported by C. M. Smith in his study of housing conditions and respiratory disease in Glasgow.<sup>3</sup> This also was in a measure an economic survey. The prevalence of respiratory disease was studied in two Glasgow areas, one a poor-class quarter, a slum district, and the other a rehousing area. The latter corresponds to our model tenement developments. The survey covered an entire year. The inhabitants of the two areas, numbering about 1,000 each, were in comparable economic states, but the housing facilities in one group were presumably much more sanitary than in the other.

To our surprise we find that there was a greater morbidity from acute respiratory disorders in the rehousing area than in the slum quarter. Here we are presented with an apparent paradox to the anticipated, and the explanations presented are based upon isolated observations rather than figures. Smith states that the results cannot be taken as evidence that improved housing conditions have been without effect on the prevalence of respiratory disease for the following reasons. In the slum district 20 per cent of the population were foreigners, chiefly Jews and Lithuanians, among whom there was less unemployment and dietary habits were better than in the rest of the population. The willingness of informants to report cases is a factor, and the author believes that reporting of illness was more accurate in the model tenement group. Theoretically, provision in the model tenement district allowed for fewer persons per room, there being only about one-fifth as much overcrowding. As a matter of fact a large proportion of the rehoused population, not long removed from the slums, continued to use just one of their several rooms for sleeping, especially in cold weather. Therefore, during the night, crowding was just as prevalent

in the rehousing district. The study illustrates beautifully some of the difficulties encountered in undertaking field surveys and drawing conclusions therefrom.

There is perhaps a natural tendency in making any statistical analysis, however small, to accept as accurate those figures which appear to substantiate what one's judgment or one's theory leads one to believe to be correct. Too often one is inclined to overlook the tremendous number of units required before all variables become negligible. The requisite total number varies, naturally, with the subject matter studied. Also, unfortunately, in many types of surveys in which statistics must be employed, sufficiently large numbers are actually not available.

This should not rule out the possibility of recourse to statistical methods, but when these are used one would do well in drawing conclusions, even though they appear entirely correct, to adopt the cautiousness manifested by Perrott, Collins and Sydenstricker, in applying conclusions only to the material studied and avoiding unjustified generalizations.

## CLINICAL AND EXPERIMENTAL

### INTRACELLULAR STRUCTURES IN MONOCYTES IN CASES OF MALIGNANT DISEASE\*

O. C. GRUSER, M.D., MONTREAL, CANADA

THE occurrence of bodies of spiral form within the large mononuclear leucocytes in cases of malignant disease was noted in 1916<sup>1</sup> but without arriving at any definite conclusion as to their nature. It was considered possible that their presence might afford a means of diagnosis.

Since that time, a search for bodies of this kind has been made in every subsequent available case, whether hospital or private (in England), and it was found that when they were present, the case was very often one of malignant disease. It was, therefore, concluded that their presence could not be accidental, or a coincidence, but that they must represent genuine structures and have a positive significance. The problem remained as to whether they were possibly mitochondrial in nature, or perhaps belonged to the category of the inclusion bodies described in the case of virus diseases by various observers.

*Technical Note.*—Ordinary air-dried blood films are used. They are stained either by Pappenheim's panoptic method or by Leishman's stain. The latter is time saving and satisfactory. No other methods of staining fulfill the requirements. A strong light is essential for the examination. The endothelioid monocytes are specially studied. When the filamentous forms are not very distinct they are traceable by searching first for their nodal points.

*Forms Noted.*—Coccoid and bacillary (batonnet) forms are well known to occur in the mononuclear leucocytes of normal blood and of exudates. They

\*From the Department of Surgery, McGill University.

Received for publication, April 24, 1933.

Under a grant for cancer research contributed by an anonymous donor.

vary in size from the ordinary azure granule to the granules and rods known as chondriomes and mitochondria found in various tissue cells. It is not these that form the subject of this communication, but linear forms; namely, (a) irregularly wavy or filamentous lines which may assume a definite spirillar form. These correspond to the chondriocentes of cytology (Fig. 1). (b) Curved or angular lines marked by nodal thickenings. Some of these are definitely flexed at the nodal thickenings and may be called "geniculate bodies." (c) Branching lines or "mycelioid" bodies. There is sometimes a round thickening at one end as shown in Cell 6 of the figure. (d) Other forms include (1) "beaded" forms, which appear as rows of fine dots lying in a linear vacuole. These correspond to

Fig. 1.—Nine cells are shown, each from a different case of malignant disease. Eight show cytoplasmic structures, and one shows an intranuclear body. Magnification: Slightly larger than that apparent with the ordinary oil immersion lens and medium high ocular. Cells 1 and 2 are hyaline leucocytes. The rest are monocytes. *Coccal forms*: Cells 1, 2, 4, 5, and 7 show the ordinary fine azure granules. Cell 1 also shows a single granule in a vacuole and a diploid body in a vacuole. *Undulant and spiral forms* are shown in cells 3, 4, 5, and 7. *Noded or beaded lines* in cells 1, 2, 4, and 5. *Spirillar form* with globular end in cell 2. *Mycelioid form* in cell 6. *Protozoal form* in cell 9. Cell 7 was considered possibly a sarcoma cell.

chondriomites of general cytology, (2) intranuclear bodies in vacuoles, showing a very fine granulation (Cell 8 of figure), (3) larger bodies occasionally occur which might easily be mistaken for protozoa.

*Possible Errors of Interpretation.*—Spiral bodies may be simulated by edges of cell substance wrinkled by spreading the film, so that an optical effect is produced. Nodal points may be passed by as being simply azure granules, the filaments being overlooked. Azure granules may appear to be connected simply

through an optical effect. Granules in intracytoplasmic clefts may appear as chondriomites. Only forms which appear definitely red or purple red are accepted as genuine intracellular structures.

| Patients definitely nonmalignant | 435                           | 67           | 56                        | 62    | 604   | 21    | 8     |

*Comment.*—The third column shows that intracellular structures of the types described occur in a high percentage of cases of carcinoma or sarcoma. Cases are counted as negative if these bodies are not seen within the conditions selected, namely during the scrutiny of between 100 and 200 leucocytes. The last column indicates how soon the bodies will be seen. Thus, in the alimentary cases, 132 out of every 1,000 mononuclear leucocytes showed them; in other words, about every eighth mononuclear.

This serves to show that this form of study can come within the scope of routine work.

As regards the first column, cases in the alimentary tract include all tumors primary in the stomach or onward, that is, not epitheliomas. The term "epithelioma" covers cases which were external or buccal or in the upper alimentary tract as far as the cardiac orifice. The negative cases in this group were mostly esophageal. Sarcomas appear to provide most of the negative results, one case was a myxosarcoma and one a fibrosarcoma; there was one case of fibromyoma turning malignant. Perhaps it is not surprising that these should yield negative results.

The cases described as "definitely nonmalignant" fall into four groups: (1) definitely healthy persons, (2) students who were apparently in good health, (3) patients admitted to hospital without organic disease as far as known (hernia, fracture, hemorrhoids), (4) various medical and surgical cases considered to be certainly nonmalignant. Some of these gave positive results. Of these, details were available in six, two being cases of suppuration, one of tuberculosis with pyopneumothorax, one of simple goiter, one of Hodgkin's disease and one a chronic mastitis (therefore possibly precancerous).

A considerable number of "suspect" cases could not be included in the table, as it was felt that pathologic confirmation was desirable before the case was eligible, considering how effectively other diseases sometimes mimic cancer.

*Patients under Radium Treatment.*—A definite fall in the proportion of patients who show these bodies is noticed, and in the others a longer search was required before they could be discovered.

No note is here made of the relation between positive findings and *stage of disease*. It has been found that even histologically, early cases may show the inclusions. But some of the "negative" results were furnished by clinically early cases.

#### DISCUSSION

Filamentous and other cytoplasmic structures are considered by cytologists to be integral components of any cell. But they are not specially referred to in textbooks on hematology as being discernible in ordinary blood films. The exact counterparts of those under discussion are, however, figured in, for instance, E. B. Wilson's classical work on *The Cell*. Similar bodies are described and discussed in the literature on virus diseases, and the question as to their nature and significance may be discussed on the same lines.

A. They may be intrinsic in the cell: (i) normal products of cell metabolism, or of growth, or of cell division. Here belong mitochondria, filamentous chondriocentes, beaded chondriosomes, lepidosomes, metachromatic, secretory, or other granules, Golgi apparatus;<sup>9</sup> (ii) nuclear in origin; chromidia, spirem threads, chromosomes; (iii) degenerative products.

One has to decide between (i), (ii), and (iii) before deciding that a given cell really contains the particular bodies in question. Granules are not noted. Hence, the difficulty of deciding whether a granule is a degenerative product or a secretory product is evaded. The position of *filamentous mitochondria* in the cell economy is also not agreed upon by cytologists. For the present purpose, it is, however, convenient to refer to these bodies as mitochondrial, though they do not give the classical staining reactions.

Definite mitochondria can be seen quite frequently in neutrophile leucocytes, especially in pyogenic infections, as well as in malignant disease, presumably owing to the depletion of the granules, which renders them visible. But the similar bodies in the monocytes do not give the same staining reaction with Leishman stain.

They may be classified as chondriosomes in that the latter are regarded as phospholipoid in nature<sup>9</sup> (pp. 47 and 223), and Giemsa will stain such material the same way as it does these bodies.

*ii. Nuclear origin:* Chromidial extrusions are commonly seen in circulating blood cells, and they have been noted especially in cases of malignant disease. They are also numerous in health under a purin rich diet.<sup>3</sup> But these extrusions never attain the length of the bodies in question; they are of drumstick or spiculated form. Perhaps the occurrence of long ex-nuclear lines likewise denotes increased nuclear activity, material passing out into the cytoplasm.

The noded lines may be of nuclear origin also, if one regards the cytoplasm as permeated by canaliculi down which granules of nuclear matter proceed outward into the circumcellular fluid. The internodal lines would then be taken as optical effects produced by the canaliculi. The mycelioid forms might be

explained in a similar manner, the extranuclear material running into the canalicular network without separating into droplets or granules.

Such an explanation would justify taking the presence of these bodies in general as an *index of chromoplasmic activity*, and this would be in harmony with the generally favored view as to the nature of malignant disease.

The noded lines bear a resemblance to kinn threads. But this is likely to be accidental, for there is no reason why they should enter the cytoplasmic canals, especially considering that circulating leucocytes do not undergo mitosis. Portions of chromatin have, therefore, no opportunity to become detached or to fail to reenter daughter nuclei. In any event iron hematoxylin has not shown their presence.

B. They may be extrinsic to the cell. (i) Nonspecific to malignant disease: (a) artefacts, such as contamination with extraneous objects, pseudoparasitoses, physical staining effects; (b) phagocytosed organisms. (ii) Specific to the disease (a) in etiologic relationship, (b) not so.

Re (i) (b). In favor: (1) The Staining reaction. On the one hand, ordinary pathogenic bacteria do not stain red with Leishman stain, whether free or within neutrophile leucocytes. On the other, experiments made by me have shown that protozoa and mycomycetes from insect intestine stain the same color as to these mitochondrial bodies after phagocytosis by human leucocytes, using opsonic technic. In the case of the leucocytes in malignant disease both neutrophiles and monocytes may show the bodies, yet those in the neutrophiles stain like ordinary bacteria, whereas the others take on the red color. It is, therefore, feasible that one is dealing with phagocytosis in each case, but the type of organism is different or its reaction in the cell is different. (2) Carcinomatous tissue frequently contains bacteria. Ulcerated tumors are necessarily infected. But even other tumors prove to contain various organisms. It would appear that neoplastic tissue attracts various organisms which may be circulating (as they do even in health), so that they gradually accumulate in the tissue.<sup>8</sup> A number of recent publications discuss the bacterial content of tumors and suggest it as a cause of increased virulence of the neoplasm, especially in the cervix cases.<sup>1, 7</sup> In fact, bacteria might even be necessary to the growth of the neoplasm, so that the therapeutic attack should commence upon them.

Now the flora of these infected tumors is multiple. They, therefore, may provide both types, those taken up by the neutrophiles, and those by the macrophages, with the corresponding difference in staining effect. (3) Histologic study shows that there is at least every opportunity for both orders of cells (invariably present in and among the tumor cells) to take up these organisms and return to the blood. Fragments of mycelium, and noded or geniculate bodies have been identified in specimens from cases in which the blood has shown the inclusions.

Against: (1) even though ingested by monocytes, even the higher bacteria should be stainable with special bacterial stains, yet they are not. (2) There must be enormous numbers of these organisms circulating in the cancer case, seeing that some are present in every cubic millimeter.

Re ii. (Are they specific?) (a) In etiologic relationship? In favor: (1)

#### DISCUSSION

Filamentous and other cytoplasmic structures are considered by cytologists to be integral components of any cell. But they are not specially referred to in textbooks on hematology as being discernible in ordinary blood films. The exact counterparts of those under discussion are, however, figured in, for instance, E. B. Wilson's classical work on *The Cell*. Similar bodies are described and discussed in the literature on virus diseases, and the question as to their nature and significance may be discussed on the same lines.

A. They may be intrinsic in the cell: (i) normal products of cell metabolism, or of growth, or of cell division. Here belong mitochondria, filamentous chondriocentes, beaded chondriosomes, lepidosomes, metachromatic, secretory, or other granules, Golgi apparatus;<sup>9</sup> (ii) nuclear in origin; chromidia, spirem threads, chromosomes; (iii) degenerative products.

One has to decide between (i), (ii), and (iii) before deciding that a given cell really contains the particular bodies in question. Granules are not noted. Hence, the difficulty of deciding whether a granule is a degenerative product or a secretory product is evaded. The position of *filamentous mitochondria* in the cell economy is also not agreed upon by cytologists. For the present purpose, it is, however, convenient to refer to these bodies as mitochondrial, though they do not give the classical staining reactions.

Definite mitochondria can be seen quite frequently in neutrophile leucocytes, especially in pyogenic infections, as well as in malignant disease, presumably owing to the depletion of the granules, which renders them visible. But the similar bodies in the monocytes do not give the same staining reaction with Leishman stain.

They may be classified as chondriosomes in that the latter are regarded as phospholipoid in nature<sup>9</sup> (pp. 47 and 223), and Giemsa will stain such material the same way as it does these bodies.

ii. *Nuclear origin*: Chromidial extrusions are commonly seen in circulating blood cells, and they have been noted especially in cases of malignant disease. They are also numerous in health under a purin rich diet.<sup>3</sup> But these extrusions never attain the length of the bodies in question; they are of drumstick or spiculated form. Perhaps the occurrence of long ex-nuclear lines likewise denotes increased nuclear activity, material passing out into the cytoplasm.

The noded lines may be of nuclear origin also, if one regards the cytoplasm as permeated by canaliculi down which granules of nuclear matter proceed outward into the circumcellular fluid. The internodal lines would then be taken as optical effects produced by the canaliculi. The mycelioid forms might be

explained in a similar manner, the ex-nuclear material running into the canalicular network without separating into droplets or granules.

Such an explanation would justify taking the presence of these bodies in general as an index of chromoplasmic activity, and this would be in harmony with the generally favored view as to the nature of malignant disease.

The noded lines bear a resemblance to linin threads. But this is likely to be accidental, for there is no reason why they should enter the cytoplasm *en masse*, especially considering that circulating leucocytes do not undergo mitosis. Portions of chromatin have, therefore, no opportunity to become detached or to fail to reenter daughter nuclei. In any event iron hematoxylin has not shown their presence.

B. They may be extrinsic to the cell. (i) Nonspecific to malignant disease: (a) artefacts, such as contamination with extraneous objects, pseudospirochetes, physical staining effects; (b) phagocytosed organisms. (ii) Specific to the disease (a) in etiologic relationship, (b) not so.

Re (i) (b). In favor: (1) The Staining reaction. On the one hand, ordinary pathogenic bacteria do not stain red with Leishman stain, whether free or within neutrophile leucocytes. On the other, experiments made by me have shown that protozoa and mycomycetes from insect intestine stain the same color as to these mitochondrial bodies after phagocytosis by human leucocytes, using osponic technic. In the case of the leucocytes in malignant disease both neutrophiles and monocytes may show the bodies, yet those in the neutrophiles stain like ordinary bacteria, whereas the others take on the red color. It is, therefore, feasible that one is dealing with phagocytosis in each case, but the type of organism is different or its reaction in the cell is different. (2) Carcinomatous tissue frequently contains bacteria. Ulcerated tumors are necessarily infected. But even other tumors prove to contain various organisms. It would appear that neoplastic tissue attracts various organisms which may be circulating (as they do even in health), so that they gradually accumulate in the tissue.<sup>8</sup> A number of recent publications discuss the bacterial content of tumors and suggest it as a cause of increased virulence of the neoplasm, especially in the cervix cases.<sup>1, 7</sup> In fact, bacteria might even be necessary to the growth of the neoplasm, so that the therapeutic attack should commence upon them.

Now the flora of these infected tumors is multiple. They, therefore, may provide both types, those taken up by the neutrophiles, and those by the macrophages, with the corresponding difference in staining effect. (3) Histologic study shows that there is at least every opportunity for both orders of cells (invariably present in and among the tumor cells) to take up these organisms and return to the blood. Fragments of mycelium, and noded or geniculate bodies have been identified in specimens from cases in which the blood has shown the inclusions.

Against: (1) even though ingested by monocytes, even the higher bacteria should be stainable with special bacterial stains, yet they are not. (2) There must be enormous numbers of these organisms circulating in the cancer case, seeing that some are present in every cubic millimeter.

Re ii. (Are they specific?) (a) In etiologic relationship? In favor: (1)

They are found in the tumor cells also; (2) some authorities on virus diseases incline to the idea that the inclusions in those diseases are specific; (3) absence of ordinary staining reaction for known bacteria (at one time the mycelium of actinomycosis could not be demonstrated in the tissue-lesion); (4) the nodes in the geniculate bodies may be similar in function to the arthrospores of streptococci, etc., or of streptothrix.

Against: (1) The evidence that they may be simply phagocyted organisms which certainly do not cause cancer; (2) tumor cells are able to phagocyte such organisms (but the presence of such bodies is taken as itself evidence that tumor cells can ingest organisms); (3) most workers do not regard inclusion bodies in virus diseases as causal (on the other hand, this is merely an expression of opinion, either way); (4) they have not the individuality, e.g., of malarial plasmodia.

(b) Not in etiologic relationship? That is, are these bodies not the actual virus, but vectors of virus? In favor: (1) There is nothing intrinsically impossible in ex-nuclear material being a bearer of ferment or zymogen, seeing that intracellular ferments must inhere in some concrete cell constituent anyway. Therefore, such material can equally harbor a virus. (2) There is the analogy of the chromosomes, which bear highly complex potentialities.

Whatever be the origin and nature of these bodies, there remains one practical fact, namely, that the subject of malignant disease has his blood "loaded" with the material in question, even at an early stage in the case. Therefore, if the answer to question B ii (a) is positive, it would mean that the monocytes carry virus about the body, and that metastases might arise even if tumor cells did not become detached. The whole body would be diseased almost from the outset, and it would not be a matter simply of an initial local lesion. But if the answer to question A ii be positive, the findings in the blood films would be interpreted in the sense of a nonspecific chromoplastic activity, and one would understand why such conditions as extensive abscess formation sometimes also furnish similar bodies in the blood cells.

On that last view, the findings may simply reflect the outpouring of cytotoxic and cytotoxic products by the neoplasm itself, an event which need not be continuous, and need not occur in all stages. The new tissue may be "closed" by fibrosis, or "open" (only a lymphocyte barrier). In the former case the mononuclear leucocytes reveal nothing, whilst in the other case they contain these bodies. It has been found in the course of this study that the blood is actually not always equally rich in the mitochondrial bodies even at all times in the day. The nucleo-irritative products seem, therefore, to vary in amount, apart from the defensive tissue reaction. Perhaps this defensive reaction explains the disappearance of the inclusions after successful radium therapy.

It may be noted that in a few cases the benign or malignant nature of a palpable tumor could be decided correctly by means of this search for cell inclusions.

#### SUMMARY

A description is given of certain filamentous, spirillar, and geniculate structures seen in (especially) the monocytes in a high percentage of cases of malignant disease, and in very few cases which were clinically nonmalignant.

They are demonstrable only with Giemsa staining or by Leishman's stain.  
They may disappear from the blood after successful radium therapy.  
Their possible nature is discussed.

During the past year, liberal facilities for bringing this study to maturity were furnished by Dr. E. W. Archibald, Director of the Department of Surgery of McGill University, so that material became accessible from the Royal Victoria Hospital, the Montreal General Hospital, and other hospitals in Montreal. Thankful acknowledgment is here extended to the physicians and surgeons who placed their cases at disposal.

## THE TOXEMIAS OF PREGNANCY\*

### II. THE NITROGEN METABOLISM

ALLAN WINTER ROWE, PH.D., MARY A. McMANUS, A.B., AND GERTRUDE A. RILEY, A.B., BOSTON, MASS.

IN A previous communication<sup>1</sup> the senior author has discussed some evidences of the hepatic factor in the group of widely diverse conditions generally called the "toxemias of pregnancy." These evidences were among the results of an elaborate chemical and laboratory study of fifty pregnant women who exhibited some one of these toxic conditions.

The basis of selection, the method of study, and the general composition of the group have already been considered in the paper noted above.

Data derived from the study of seventy-seven women studied repeatedly both throughout a normal pregnancy and for a number of weeks thereafter,<sup>2</sup> have served as a control; these will be drawn upon, as needed, for the present discussion.

This present paper is concerned with the protein metabolism, as evidenced chiefly in the levels of blood and urine nitrogen.

\*From the Evans Memorial, Massachusetts Memorial Hospitals.  
Received for publication, July 31, 1933.

<sup>2</sup>Read before the Section on Pathology and Physiology at the Eighty-Fourth Annual Session of the American Medical Association, Milwaukee, June 16, 1933.

The normal group was in part drawn from institutions for unmarried mothers, who were usually young primiparas. The toxemia group were older women, only one-third of whom were in their first pregnancy and not a few of whom gave histories of extensive childbearing. No evidence was forthcoming in the study that repeated fetation led to results differing from those characterizing the primiparas.

The time of study of the individual members of the toxic group was varied. Three-fourths of the patients fell in the last three months; the remainder showed only a general distribution.

In considering the protein exchange, the total nitrogen in the urine is

Chart 1.

significant as a measure of the absolute protein utilization, since skin elimination under most circumstances is but an inconsiderable fraction. Further, the independent quantitation of several individual components whose summation determines the total value is significant, as the metabolic origins of each fraction are widely differentiated. The original metabolized protein is the sole factor common to them all. To illustrate, urea is the indifferent form in which the principal amino-acid waste is eliminated, while ammonia, on the other hand, is the end-result of a defense mechanism mediated by the kidney to aid in the elimination of certain acid metabolites without depleting the blood of its essential fixed alkali. The so-called "nitrogen partition" deals with the four major components, urea, uric acid, ammonia, and cre-

atinine, and then assembles the remainder of the numerous nitrogen-containing substances into a single fraction called the "residual" nitrogen, which is determined by difference. Folin<sup>1</sup> established certain criteria for normal partition values and the few later studies on normals (Matthews,<sup>1a</sup> Long and Gephart,<sup>1b</sup> Rowe and Proctor<sup>1c</sup>) have been broadly confirmatory. The last authors<sup>1c</sup> confirmed earlier observations that the residual fraction showed a relative increase when the total nitrogen was diminished and by a synthesis from their own data, with those of Folin (l.c.) and Smith,<sup>2</sup> defined the curve representing this relationship.

Briefly, with a total elimination exceeding 8 gm., there is seemingly a fixed relationship at something less than 6 per cent. At levels slightly below this minimum the curve takes a sharp progressive upward trend and soon assumes large magnitudes. In a number of studies the senior author has defined the upper normal level of residual nitrogen at 9 per cent where the total elimination indicates a protein exchange above the conventional main-

Chart 2.

tenance level of 7 gm. of  $N_2$ . Further, he has shown that values above this rather generous limit are one general index of a disturbed metabolism arising from a very wide variety of causes. This value then assumes a special significance in the assessment of the normality of the individual metabolism. In an earlier paper<sup>6</sup> dealing with the normal control group, the average nitrogen elimination was reported as relatively constant, at least during the last twenty-four weeks of pregnancy, and lying at a level slightly superior to maintenance. When one remembers, however, that the mother is storing protein in amounts far in excess of fetal needs, the adequacy of the catabolic exchange shown by the urine level assumes an added significance.

Turning now to the actual results of the study, the significant figures are grouped in tabular form (Table I).

The identity of the two total nitrogen values in the normal series ante- and postpartum, is fortuitous. Comment should be made, however, on the fact that following delivery the antepartum storage seems to be replaced by a different factor which also produces the common end-result of low urine

TABLE I  
NITROGEN PARTITION IN URINE

| DATUM                               | NORMAL |      | TOXIC |      |
|-------------------------------------|--------|------|-------|------|
|                                     | A.P.   | P.P. | A.P.  | P.P. |
| Total nitrogen (gm.)                | 8.03   | 8.04 | 6.93  | 8.33 |
| Urea nitrogen (%)                   | 79.6   | 80.8 | 77.8  | 80.8 |
| Uric acid nitrogen (%)              | 2.8    | 1.9  | 3.1   | 2.8  |
| Ammonia nitrogen (%)                | 5.0    | 5.1  | 4.2   | 3.3  |
| Creatinine nitrogen (%)             | 4.7    | 4.2  | 4.7   | 3.7  |
| Residual nitrogen (%)               | 7.9    | 8.0  | 10.2  | 9.4  |
| Per cent with residual more than 9% | 37     | 33   | 65    | 48   |

nitrogen. Naturally, the actual loss of protein through the breast milk comes into consideration here. Urea is slightly low in both periods, though post-partum it evidences a possible beginning recovery to the usual normal levels. This is no more than yet another report of the low urea which has come to be

Chart 3.

recognized as a normal feature of pregnancy. A high uric acid during pregnancy shows a drop to a more normal level when the strain of gestation is removed; ammonia is slightly but definitely high; the average for residual nitrogen is well within the normal range, but about one-third of the series show values which are absolutely high.

In the toxic group, several differences at once present indicating the general disturbance of metabolism associated with the toxic status. The total nitrogen is significantly lower. Even though this could result from an impaired appetite and lowered food intake it would still be an evidence of toxicity. To render this depression more apparent, the individual measurements are plotted in Chart 3. The curve marked "normal" derives from the average data of the control series and serves as a delimiting boundary. But few of the observations fall above its level, while the great majority are significantly below.

Of the other figures, urea is still lower, uric acid still higher, while the residual fraction is frankly above the liberal allowance for the normal, and two-thirds of the group participate in this departure. With the emptying of the uterus, the nitrogen rises to a level normal in relation to the control group, urea rises relatively and absolutely, and the residual nitrogen falls both in amount and in the frequency of report of high levels. As these women were examined during the fortnight following delivery, the time factor bulks large and the trend toward normality becomes even more significant of a changed status. Ammonia is lower in the toxic than in the normal series. In the postpartum period it more closely approaches the conventional normal than does that in the control series. Loss of fixed alkali through the milk should affect both groups equally and the explanation of the anomaly is not directly forthcoming. The originally high uric acid shows a slight downward trend but remains at a height which is frankly above the normal. Probably this reflects the hepatic factor present in so many of the cases; hepatic dysfunction is known to modify purin metabolism, and these cases present a functional derangement which but slowly returns to the normal. The liver complement in the picture could also account for the high residual nitrogen figures.

To summarize this section briefly, pregnancy as such, produces changes in the urine nitrogen suggestive of some degree of toxemia, while actual toxicity during this condition accentuates these changes. Further, with the removal of the common causal factor of gestation by delivery, even in the toxic group there is evidence of a prompt retrograde movement toward normal relationships.

The various dissolved nitrogen-containing substances in the blood usually designated as the "nonprotein nitrogen" are, with but one significant exception, ammonia, the forerunners of the urine nitrogen in its many subdivisions.

In reviewing what may be designated as the "nitrogen partition" of the blood, only the ammonia is lacking from the group. Convention and propriety further dictate a different method of recording the blood constituents to express more significantly the meaning of departures from the normal. The urine is a summation of the various secreting levels of the twenty-four hours during which, by thermodynamic work, the blood is concentrated to form the urine. This collects in the bladder, a container inside the body, and is emptied from it at intervals into other containers only relatively more remote from the secreting agent. The blood, on the other hand, is the channel of ingress and egress of foodstuffs and wastes, and the levels of its several constituents are maintained at a relative constancy through the agency of the vast number of individual factors contributing to the continuance of homeostasis. Under the force of superimposed effects, new equilibria are established at other levels but the tendency always is to return to the earlier conditions when the extraneous agencies cease to operate. If the pressure be not too great, the homeostatic influences tend to compensate for such effects and restore or maintain normal levels even during the continued operation of the added effect. Temporary changes in blood sugar levels during sugar absorption

and the maintenance of blood  $P_{II}$  in compensated ketosis are typical illustrations. The absolute levels in the blood thus assume a significance that in the urine is largely absorbed by the single factor of the total nitrogen. The average blood levels ante- and postpartum in the two series are collected in Table II.

TABLE II  
BLOOD NITROGEN

| DATUM                     | NORMAL |      | TOXIC |      |
|---------------------------|--------|------|-------|------|
|                           | A.P.   | P.P. | A.P.  | P.P. |
| Nonprotein nitrogen (mg.) | 25     | 32   | 28    | 32   |
| Urea nitrogen (mg.)       | 12     | 16   | 14    | 15+  |
| Uric acid (mg.)           | 3.3    | 3.7  | 3.6   | 3.6  |
| Creatinine (mg.)          | 1.5    | 1.5  | 1.5   | 1.5  |
| Residual nitrogen (mg.)   | 11.3   | 14.2 | 12.2  | 15.2 |

It has long been a well-recognized fact that the nonprotein nitrogen and its composing fractions are, in the main, definitely depressed during pregnancy. We have never been able to record the sharp additional decline in blood urea to levels approaching 30 per cent of the whole, reported by several observers; we have uniformly found the values in pregnancy to coincide with those in normal males and nonpregnant females, or from 45 per cent to 50 per cent. In the present instance both series show an entirely normal relationship. On the other hand, uric acid values show a modest upward tendency, although in normal pregnancy individual values may fall within the conventional normal limits. In relation to the nonprotein nitrogen, however, the uric acid values are definitely high. It is apparent that antepartum all of the values, barring creatinine and uric acid, are definitely low, and that delivery engenders a prompt return to normal levels. In the toxic series, the values antepartum are all somewhat higher, a presumptive evidence of low-grade retention that is in harmony with the recognized renal influence in this condition. After delivery the blood reverts to normal levels that are very close to those of the normal controls. Recognizing that the homeostatic agencies operate most effectively in the blood stream and that existing chemical methods are incompetent to record very small variations, the blood levels fail to give evidence of that slower return to normal levels that is clearly shown by the urine data from the toxic group.

To summarize briefly, pregnancy causes a lowering of the nitrogenous constituents of the blood, uric acid excepted, which is less marked in cases of toxemia as the renal element here introduces an opposing influence. Both normal and toxic pregnancies tend to revert to the usual blood levels shortly after delivery.

#### CONCLUSION

1. The blood and urine data reflecting the protein metabolism have been determined in series of normal and toxic pregnant women.
2. Characteristic urine findings are recorded with pregnant patients; the hepatic and renal features of toxemia are superimposed influences adding their special effects to those of the basic condition.

3. Termination of pregnancy initiates a return to normal levels, the latter less rapid in the toxic group.

4. Blood nitrogen levels are low in normal pregnancy. Toxemia tends to develop the renal influence as an opposing agency.

5. Restoration to normal blood levels follows rapidly on the termination of the pregnancy in both study groups.

The authors express their indebtedness to all who have participated in the study.

## VERRUCOUS AORTITIS WITH SPECIAL REGARD TO ANEURYSM FORMATION IN CHILDREN\*

BENJAMIN H. NEIMAN, M.D., CHICAGO, ILL.

FOR a long time, nonsuppurative inflammatory lesions in the aorta were attributed chiefly to syphilis, a conception first expressed by Doehle in 1885 and later in 1899 by Heller.<sup>1</sup> The "Doehle-Hellersche Aortitis" held sway over medical thought until more recent investigations revealed that acute infectious diseases as typhoid fever, typhus, influenza, and scarlet fever, may also cause inflammatory changes in the aorta (Siegmond<sup>2</sup>). Of particular importance, however, is the fact that rheumatic fever seems quite frequently to leave its mark on the large arteries (Klotz,<sup>15</sup> Pappenheimer and von Glahn<sup>16</sup>).

Although inflammatory changes in the aorta were suspected in the course of rheumatic fever, no sustained effort to define the histologic features was made until the work of Klotz<sup>15</sup> in 1912. Clinically, the diagnosis has been made many times, but it is unverified by autopsy.

To this category of unverified diagnoses belong the reports of Bouillaud<sup>3</sup> (1840), Roger<sup>4</sup> (1863), LeLong<sup>5</sup> (1869), Lauenstein<sup>6</sup> (1876), Leger<sup>7</sup> (1877), Marfan<sup>8</sup> (1901), Méry et Guillemont<sup>9</sup> (1902), La Rue<sup>10</sup> (1903), Renon<sup>11</sup> (1905), Weil et Menard<sup>12</sup> (1912). Bernert<sup>13</sup> (1910) deserves the credit for calling at-

Received for publication, August 12, 1933.

tention to the fact that many of the previously reported cases, cited as rheumatic in origin, were probably examples of mycotic aneurysms. Rabé<sup>14</sup> (1912) was the first to present histologic findings.

In 1912 the first serious effort was made by Oskar Klotz<sup>15</sup> to study the histologic lesions in the aorta occurring as a result of rheumatic infection. In 15 cases of rheumatism which came to necropsy, he had 3 patients, aged nine, sixteen, and twenty years, dying during the first attack of rheumatic fever; 4 cases of patients, aged twenty-eight, thirty, thirty-six and forty-four, with history of recurrent attacks; and 8 cases of patients with chronic rheumatism, all of whom had suffered from recurrent or progressive heart disease associated with rheumatic fever. He concludes that there appears to be a fairly definite form of arterial disease which is associated with rheumatic fever in its different stages. The arteries react to the irritant in a true inflammation, and this reaction is observed in the adventitia and the outer portion of the media. In the acute stages, the inflammatory exudate is of the nonsuppurative variety in which the lymphoid cell is most prominent. The inflammation occurs particularly in the neighborhood of the smaller arteries, while the medium-sized vessels are little affected. On the other hand, the larger arteries, which are supplied in their outer coats by nutrient vessels, are damaged by the inflammatory process, which travels along the vasa vasorum. He observed, that during the acute process, the changes in the aorta consist of a destruction of tissue noted in the loss of muscle and elastic elements. Similar degenerations are common in the heart. At times the degenerative processes are extensive, leading to the loss of considerable tissue in, and probably weakening of, the media. The intima of the arteries, he states, does not appear to be primarily affected. In the early stages, slight superficial fatty changes are sometimes noted, while later in the chronic stages the intima proliferates, giving rise to a nodular endarteritis.

In 76 cases of acute rheumatic fever, Pappenheimer and von Glahn<sup>16</sup> found the distinctive lesion of the aorta to be a scar, roughly the shape of an inverted wedge, often acellular and located in the region of the nutrient vessels of the media. This type of arterial lesion was not found in a comparative study of 77 nonrheumatic cases, with the exception of one, in which death resulted from pneumococcal meningitis. In the aortic adventitia, they found specific changes consisting of the presence, in some cases, of typical Aschoff cells, showing, however, little tendency for grouping. These cells, they regard as diagnostic. They are rounded or oval. The cytoplasm is basophilic and stains intensely with pyronin. The nuclei each have a distinct nucleolus, and the cells seem to be arranged about degenerating collagen fibers. In their second communication on this subject, the authors described earlier reactions in the media to support the view that the perivascular medial scars are the sequelae of an earlier focal perivascular inflammatory lesion.

Following the first paper by Pappenheimer and von Glahn, many communications began to appear, both in American and European literature, giving histologic evidence of destructive effects of rheumatic fever on the aorta (Weisl,<sup>29</sup> Besançon and Weil<sup>30</sup>), even so severe as to lead to aneurysm formation (Gray and Aitken<sup>31</sup>).

Changes in the adventitia of the aorta were further emphasized as perivascular round cell accumulations and nodular fibrosis (Chiari,<sup>18</sup> Barnard<sup>20</sup>). Clawson<sup>21</sup> injected *Streptococci viridans* intravenously into monkeys and produced changes in the media and adventitia similar to those seen in rheumatic fever. He also gave subcutaneous administrations of the cocci to rabbits but produced only subcutaneous nodules similar to those described by Swift<sup>22</sup> and Frank.<sup>23</sup>

Sacks,<sup>24</sup> in his review of the pathology of rheumatic fever, states that since the vasa of the pulmonary artery are derived from the coronary arteries, lesions in this artery are to be expected. Kugel and Epstein,<sup>24</sup> on the basis of this supposition, examined a series of 24 cases of rheumatic fever and found 5 in which there were histologic evidences of active inflammatory changes in the pulmonary artery. The changes in the pulmonary artery were of two types; namely, a diffuse cellular infiltration in the intima and subintimal layers of the media and focal perivascular accumulation of cells comparable to the Aschoff nodule in the myocardium. In 2 cases, there were macroscopic changes in the intima consisting of small, raised, dull gray yellow patches of irregular outline. In 2, there was a disruption of the elastic fibers of the media, almost as conspicuous as in syphilis. In 14 cases, the pulmonary valve was involved showing an interstitial valvulitis. In 3 cases, Aschoff bodies and in 6 verrucae were found. In 17 cases, in which there were changes in the musculoarterial junction, Aschoff bodies were found in a few. The aorta was involved in 22 cases. In 4 cases, gross lesions in the intima were present. As controls, they used 31 cases in which there was a nonrheumatic pericarditis, and in 75 cases no pericarditis or rheumatic cardiac disease was present. They found nothing in any of the controls which was in any way confusing.

Destructive lesions in the media with extensive scarring were also reported by Paul,<sup>27</sup> in the course of rheumatic fever, and Wätjan<sup>26</sup> observed Aschoff bodies in the epicardial fat over the anterior surface of the pulmonary artery. Gotthardt<sup>25</sup> reported a case of verrucous endocarditis of all the valves and fibrinous pericarditis which were accompanied by an endarteritis of the pulmonary artery. Chiari<sup>19</sup> found a fibrosis of the adventitia of this artery.

#### PRESENTATION OF CASES

In a series of 4,100 consecutive autopsies, 3 cases have been found in which there was a verrucous lesion on the intima of the aorta.

CASE 1.—An Italian female child, eleven years old, entered the Cook County Hospital on March 8, 1932. She was apparently well until two weeks prior to entrance when she developed pain over the heart, cough, and fever. On the day of entrance into the hospital, she had a moderate nose bleed.

The birth and development history was negative.

The child had had measles and chickenpox.

On physical examination, the patient was found to be well nourished but somewhat undersized. The temperature was 102.4° F.; pulse, 124; respiration, 28; and blood pressure, 140/60. The skin was dark and there was long, dark hair over the upper lip and along the side of the cheek, on the back and a little over the lower extremities. The pubic hair was luxurious and of female distribution. There were diffuse coarse râles heard over both lung fields.

The heart was enlarged transversely and there was a soft, systolic thrill and a systolic and diastolic murmur over the apex. Over the aortic area, indistinct murmurs were heard.

The pulse at the wrist was forceful, of high pulse pressure, quickly striking the finger and receding. The carotid pulsations were easily visible. The femoral, popliteal, dorsalis pedis, and posterior tibial arteries were not palpable, nor could they be detected by the blood pressure apparatus.

The liver was palpable, but the spleen was not.

The white blood count was 20,100 with 84 per cent polymorphonuclear leucocytes. There were many macrocytes present. Polychromatophilia and anisocytosis were evident. The urine was negative as was also the blood Wassermann.

The clinical diagnosis was endocarditis of the aortic and mitral valves, diffuse bronchopneumonia, and coarctation of the aorta.

While in the ward, the patient was rather comfortable but ran a low grade remittent fever of 99° to 100° F. The findings in her lungs spread gradually. About one week after entering the ward, the child was seen sitting up in bed and resting quietly but coughing frequently. Forty-five minutes later, she was found on the floor dead.

*Autopsy.*—(Performed by Dr. R. H. Jaffé.) The essential findings were in the heart, aorta, and incidental interesting findings in the genitalia.

The heart weighed 250 gm. The wall of the left ventricle measured 12 mm., and that of the right ventricle 5 mm. in thickness. The epicardium was thin, transparent, smooth, and shiny. The apex was formed by the left ventricle. The myocardium was purple, gray and friable. The transverse and vertical diameters of the left ventricle were 8.5 cm. The trabeculae and papillary muscles were slightly flattened. On the auricular surface of both cusps of the mitral valve, were present pinhead-sized, granular, firm, and slightly transparent nodules. The free edges of the aortic leaflets were thickened and rounded, and along the limbus there were firm, sandlike, granular deposits present.

The aorta measured 52 mm. in circumference above the valve. About 1 cm. above the aortic valve, there was an oblique, transverse tear which was 35 mm. wide. The edges of the tear were indented, and 2 mm. longitudinal bridge of intact wall separated the tear into a larger right and smaller left portion. The floor of the tear exposed a thin, pink gray membrane with fine, longitudinal lines and small, granular elevations. The adventitia was injected. To the right, the tear terminated in an irregular, slightly depressed, light brown area. In the ascending aorta, there were several up to 25 × 4 mm. streaklike, light yellow areas. Just beyond the origin of the left subclavian artery, the lumen of the aorta becomes suddenly narrowed to a diameter of about 1 mm. Beyond the narrowed portion, the circumference of the aorta widened to about 58 mm. Small, light yellow plaques were found in the upper wall of the arch. At the diaphragm, the circumference of the aorta was 36 mm., and below the origin of the renal arteries it was 22 mm.

Above the bifurcation of the aorta, there was a worm-shaped, loose, cylindrical, light pink gray blood clot 55 mm. long and 10 mm. in transverse diameter. The lower end of the blood clot projected into a flagellum-like extension 35 mm. long. The upper end terminated into a pointed projection 3 mm. long. The circumference of the aorta above the bifurcation was 18 mm. The internal mammary artery had a circumference of 6 mm.

The uterus measured 45 by 25 by 8 mm.

*External genitalia:* The clitoris was about twice the normal size. The vestibulum vaginae and vagina were well developed. The vulva appeared rather narrow because of an enlargement of the labia minora.

*Ovaries:* The right ovary was replaced by an ovoid body, 18 by 10 by 6 mm. in diameter, which showed a distinct, light pink yellow capsule, and on sectioning, was found to be composed of a finely granular, light yellow tissue. The left ovary was missing, and in its place was found a ridge 25 mm. wide and 3 mm. high.

## Microscopic examination:

**Aorta:** The tear in the ascending portion of the aorta involved the intima and the entire media and exposed the adventitia which was densely infiltrated by polymorphonuclear leucocytes. Approaching the tear, the intima became slightly thickened, and in the region of the tear, was everted, covering the edges of the torn structures. The thickening of the intima resulted from a cellular accumulation between endothelium and internal elastic membrane. Delicate elastic fibrils were separated by swollen fibrocytes with large, pale nuclei, small round cells, and histocytic elements with an ample cytoplasm and round or oval nuclei. There were bizarre-shaped, drawn out nuclei free between the intact cells. The internal elastic membrane was split into several layers and in the everted portion showed areas frayed to the extent that it was completely interrupted. Near the torn portion, the muscle and elastic fibers of the media passed rather abruptly into a zone of complete necrosis without structural differentiation and scanty chromatin granules. The necrotic area stained from brass yellow to deep yellow brown after van Gieson and pink red with eosin. In the outer portion of the media, single mononuclear elements were wedged in between trabeculae of necrotic tissue,

Fig. 1.—(Case 1.) Aorta. Section taken through the area of rupture. Elastica stain ( $\times 100$ ).

and the necrosis extended for a short distance beyond the tear along the external elastic membrane. In the floor of the defect, there were only a few small segments of the external elastic membrane visible.

Between the polymorphonuclear leucocytes which infiltrated the adventitia, were found single, large, degenerating fibrocytes, the nuclei of which could assume very irregular forms. Elastic fibrils were practically absent.

Away from the tear, the intima appeared well preserved. In the media, there were circumscribed areas of increase of the metachromatic substance which spread apart the elastic elements. Near the outer elastic membrane, there were small areas in which the coarse elastic fibers seemed to have disappeared while the fine fibrils still could be recognized. The adventitia was of distinctly increased cellularity. The fibrocytes were swollen, often separated and mobilized. There were many mononuclear cells with a distinct rim of cytoplasm, and lymphocytes and a few oxyphilic leucocytes. In addition to these cell forms, elongated cells were found with pyknotic, crenated and elongated nuclei, which could be seen also between the muscle fibers of the adjacent portion of the media.

**Myocardium:** There were in the myocardium, numerous nodular accumulations of large cells which were located near the larger blood vessels. The cells which formed the nodules

had a pale stained cytoplasm and oval nuclei with a central indented spindle of chromatin. These cells centered about areas of fibrinoid necrosis. Between them, a few lymphocytes and leucocytes were found. Underneath the endocardium, areas of necrosis were found, which were surrounded by cells of histocyte type distinctly different from the cells of myocyte type. In addition to the cellular nodules, there were flame-shaped scars radiating between the muscle fibers, which were increased in thickness and the striations of which were obscured.

The anatomic diagnosis was coarctation of the aorta with thrombosis of the aorta distal to the coarctation; spontaneous rupture of the aorta above the aortic valve and rheumatic aortitis with necrosis of the media; verrucous endocarditis of the mitral and aortic valve and slight fibroplastic deformity of the aortic valve; slight excentric hypertrophy of the heart; moderate dilatation of the internal mammary and intercostal arteries; chronic passive congestion of the lungs, liver, spleen and kidneys; bronchopneumonia of the right lower pulmonary lobe; bilateral hydrothorax; follicular hyperplasia of the spleen; pseudoherniaphroditismus internus masculinus.

CASE 2.—A colored female, twenty-seven years old, entered the Cook County Hospital on April 23, 1932, stating that she had been well until one month ago. At this time, she began having periodic attacks in which her heart appeared to "jump." These attacks were followed by precordial boring pain that radiated to her left shoulder down to her left arm and seemed to stay there. The attacks were easily precipitated by any exertion or excitement. At the onset the attacks lasted but a few minutes, but recently had increased in length up to twenty minutes or more. Often during the attack, the patient fainted, but usually she had to stop immediately in her work. There was no great fear of death at any time. Occasionally nausea, vomiting, and urinary urgency followed an attack. The patient was married twice and received three injections of mercury in her buttocks in 1922.

The physical examination revealed a well-nourished colored female, lying quietly in bed and not acutely ill. The temperature was 98.8° F.; pulse, 80; respiration, 20; and the blood pressure, 106/64. The pupils reacted to light and accommodation. The heart was not enlarged; there were no murmurs or thrills. The rhythm was regular. The chest and abdomen were essentially negative. The red blood count was 3,260,000; white blood count, 7,800; and the hemoglobin 55 per cent.

The patient had several attacks during her short stay in the hospital, some slightly alleviated by amyl nitrate, others by quinidine. On the morning of the day of her death, the patient had a typical attack, which was as follows: She was sitting up quietly in bed when she suddenly toppled from her back rest, became livid, cyanotic, stopped breathing, and then broke out into a cold sweat. The pulse was imperceptible, even by auscultation. Artificial respiration was administered for five minutes and adrenalin and caffeine injected. The patient rallied but four hours later died during a similar attack. Blood for a Kahn test could not be taken during life because the prick of the needle initiated an attack. The postmortem blood Kahn reaction was 2+ positive.

*Autopsy.*—(Performed by Dr. R. H. Jaffé.) The essential pathologic findings were in the heart and in the aorta.

The circumference of the aorta was 56 mm. at the valve, 30 mm. at the diaphragm, and 26 mm. at the bifurcation. In the ascending part of the aorta, above the valve, there were light yellow, slightly raised patches. Above the commissures, were gray white, 10 mm.—areas covered by fine, sandlike, granular, light gray precipitates. These precipitates extended above the right leaflet for a distance of 20 mm. In the region of the arch, there were a few whitish areas and also a slightly raised, 10 mm., pale yellow gray plaque covered by fine granular precipitate. Throughout the descendens portion of the aorta, there were many small, light yellow plaques.

The heart weighed 220 gm. The left ventricle measured 15 mm. and the right ventricle 5 mm. in thickness. The epicardium was smooth and studded with pinpoint-sized, light pink gray patches. The myocardium was light purple pink and friable. The ventricles were dilated and the trabeculae were flattened.

### Microscopic:

**Heart:** In the inner third of the myocardium, there were irregular areas of severe alteration of the muscle fibers. The fibers had lost all structural differentiation and appeared as homogeneous bands. The nuclei were broken up into chromatin granules or were entirely missing. Between these muscle fibers could be seen a moderate number of polymorphonuclear leucocytes, and around the adjacent larger vessels were larger accumulations of these cells. Throughout the wall, many muscle fibers contained fine lipid granules. In the epicardium, there were a few small, round cell accumulations.

**Aorta:** Supravalvular verrucous area. The intima of the aorta was covered by a layer of fibrinoid material with elongated, drawn out and segmented, deeply stained nuclei. Underneath this layer, the intima was thickened and cellular. Here many fibrocytes, young, smooth muscle fibers, small round cells, and neutrophilic and oxyphilic leucocytes were found. In the center of the area, the changes terminated in a large focus of necrosis which involved not

Fig. 2.—(Case 2.) Aorta. Fully developed verruca. Hematoxylin-eosin stain (X150).

only the thickened intima, but extended also deep into the media. On the inner surface, the necrotic tissue fused with the fibrinoid layer, the point of fusion being marked by streams of degenerated pus cells with karyorrhectic nuclei. Deeper down, the necrotic material showed early calcification. In the periphery of the necrosis, were found focal accumulations of pus cells; these continued beyond the necrosis between the muscle fibers of the media which here, too, were severely degenerated and partially necrotic, while the elastic fibers were swollen up and disintegrated.

Underneath the necrosis, at the border between the media and adventitia, there was a lipid granuloma composed of pseudoxanthomatous cells, plasma cells, and small round cells, and of a few oxyphilic leucocytes. From this granuloma, tufts of cells extended into the media. In addition to the large area of necrosis, there were several smaller ones which were located in the deeper portions of the intima and in the media. They showed fine calcium deposits and were not separated from the surrounding tissue. Underneath these areas, there were perivascular accumulations of round cells, plasma cells, and eosinophilic leucocytes. The vasa vasorum had greatly thickened walls, and there were many dense accumulations of lymphocytes and plasma cells in the adventitia.

**Plaque in the Arch of the Aorta:** The inner surface of the plaque was covered by a thin layer of fibrinoid material which took the Weigert stain. Underneath this layer the intima was thickened and cellular. The fibrocytes were swollen and increased in number, and there were loosely scattered neutrophilic and oxyphilic leucocytes, small and large lymphoid round cells, and focal accumulations of plasma cells. In the center of the plaque, a large area of necrosis was present, which extended into the media without a sharp line of demarcation and contained fine calcium granules in the basal parts. From the fibrinoid surface layer, the necrotic tissue was separated by a strip of living tissue upon which followed a collection of disintegrating polymorphonuclear leucocytes with broken up and pyknotic nuclei. Bacteria could not be demonstrated in this area or in the necrotic tissue itself. In the region of the necrosis, the internal elastic membrane was completely destroyed, the destruction being preceded by a splitting into the finest fibrils. Throughout the media, there were many newly formed capillaries extending close to the intima and surrounded by lymphocytes and plasma cells. The piercing of the media by these vessels and infiltration was associated with a disappearance of the elastic fibers. The adventitia was thickened and fibrosed, and the arteries of the adventitia showed a very marked proliferation of the intima with much narrowing of the lumen. There were many focal accumulations of plasma cells and lymphocytes.

**Midportion of Aorta Ascendens:** There was a thickening of the intima with intra- and extracellular lipid deposits in the deeper portions. The internal elastic membrane was split and accumulations of fat-filled cells were present between the separated elastic structures. The capillaries, beyond the outer third of the media, were proliferated and surrounded by a slight round cell infiltration. There was a very pronounced fibrosis of the adventitia with a thickening of the walls of the vasa vasorum, and large accumulations of lymphocytes and plasma cells were present in the adventitia.

Levaditi's stain revealed many argentafin granules but no spirochetes in the necrotic tissue.

The anatomic diagnosis was verrucous aortitis; syphilitic aortitis; acute myocarditis; passive congestion of the spleen, liver, and kidneys; adhesions about the liver, spleen, and both ovaries.

**CASE 3.**—A four-year-old white female child was brought into the Cook County Hospital on July 21, 1932. The mother stated that the child was well until two weeks before entrance when it developed colicky pain in the abdomen. It was also noticed that during the past two weeks the child had had a fever in the latter part of the afternoon. Development history was normal. The mother had had no miscarriages.

The physical examination revealed a well-developed child. The temperature was 103.4° F.; pulse, 140; respiration, 26. The heart was enlarged to the left. The apex beat was displaced slightly to the right. Upon examination of the chest, the breath sounds were found to be diminished in the left midaxillary line with impairment of resonance over the left apex anteriorly. The white blood count was 29,400 with 78 per cent polymorphonuclear leucocytes. The x-ray revealed a very marked cardiac enlargement.

The clinical diagnosis was pericarditis with effusion. Five days after entrance into the hospital, a pericardial paracentesis yielded 35 c.c. of a straw-colored fluid. About ten minutes later, the child became cyanotic and expired.

**Autopsy.**—(Dr. R. H. Jaffé.) The pericardial sac extended from the right mammary line to the left anterior axillary line. The sac contained 250 c.c. of coagulated blood. The heart measured 70 mm. in vertical and 50 mm. in transverse diameters. The surface was covered by loosely adherent, granular light pink gray membranes. The wall of the left ventricle was 11 mm. and that of the right ventricle, 5 mm. in thickness. The myocardium was light purple pink and friable. The heart valves were grossly unchanged.

**Aorta:** At the valve, the aorta measured 42 mm.; at the diaphragm, 28 mm.; and at the bifurcation, 18 mm. in circumference. The intima above the valve was smooth. Beyond the arch of the aorta, 8 mm. below the opening of the left subclavian artery, located in the anterior wall, there was an oval opening 7 by 5 mm. in diameter. The edges of the opening were smooth and slightly everted. The intima was smooth except for fine, pinpoint-sized granular and slightly transparent deposits near the lower edge. The opening led into a sac

which was 7 cm. in vertical, 5 cm. in transverse, and 5 cm. in anteroposterior diameters. The sac, which was adherent to the median aspect of the left upper pulmonary lobe, bulged into the pericardial sac stretching its reflexed portion. The sac compressed slightly the left branch of the pulmonary artery. At the greatest convexity of the intrapericardial portion of the sac, there was an irregular hole 25 by 20 mm. in diameter, with indented edges. In the sac, which was lined by a whitish finely granular membrane, there was a small amount of loosely coagulated blood.

#### Microscopic examination:

**Aorta:** When the opening in the descending aorta was approached, the first change visible was the appearance of a layer of fibrinoid material which rested upon the internal elastic membrane. This fibrinoid material contained irregular, deeply stained, and shrunken nuclei. Near the opening, the layer was raised to nodular elevations which stained brass yellow after the van Gieson method. Here and there close to the internal elastic membrane, a group of better preserved oval nuclei was found forming small palisades with the nuclei

Fig. 3.—(Case 3.) Aorta at point of rupture. Hematoxylin-eosin stain ( $\times 150$ ).

perpendicular to the membrane. At the opening, the layer of fibrinoid necrosis bent outward to pass into the internal lining of the sac. The point of bending was marked by a greater cellularity, and besides cells with shrunken and indented nuclei, there were some lymphocytes and an occasional multinucleated giant cell. Underneath the nodular elevations, the media revealed very severe changes. The muscle fibers were necrotic, hyalinized, and the chromatin granules of the broken down nuclei formed fine, dustlike precipitates. At the border of the media and adventitia, the zone of necrosis extended for some distance beyond the changes of the intima in the form of a tongue-like projection. Stains for elastin demonstrated that the internal elastic membrane was destroyed underneath the nodular formations of fibrinoid material. In the necrotic area of the media, the coarser elastic fibers were still visible, but they were broken up into small pieces and curled, and the finer fibrils had disappeared. The adventitia was well preserved and contained only an occasional small accumulation of round cells.

The wall of the aneurysm was in continuation with the wall of the aorta, the layers of which could be recognized though they were severely changed. Innermost, there was a broad band of fibrinoid necrosis with shrunken, pyknotic, and broken up nuclei, which band cor-

responded to the intima and media. Immediately adjacent to the lumen, remnants of intact tissue, which caused the internal lining of the sac to be smooth could be detected. These remnants consisted of a few connective tissue trabecles with preserved fibrocyte nuclei. The connective tissue soon passed into the fibrinoid necrotic material which was particularly rich in nuclear debris in the places corresponding to the media. In these places, remnants of elastic tissue in the form of tortuous segments were found still suggesting the arrangement of the elastic tissue of the media. Near the adventitia, mononuclear cells, neutrophilic, and a few oxyphilic leucocytes were seen between the shrunken and disintegrated nuclei of the preexistent structures.

The adventitia was the only layer which had remained intact. It was very thick and was formed by dense connective tissue interspersed by a moderate number of elastic fibrils. There were many dilated capillary blood vessels present, which were often surrounded by

Fig. 4.—(Case 3.) Aorta at point of rupture. Elastica stain ( $\times 150$ ).

accumulations of lymphocytes, plasma cells, histocytes, and a few leucocytes. Gram-Weigert stain demonstrated single gram-positive diplococci and streptococci in the nodular elevations on the inside of the aorta. These cocci became abundant in the region of leucocytic-histocytic infiltrations of the aneurysmal sac where they were found also inside of mononuclear and polymorphonuclear elements.

Sections taken from other portions of the aorta did not show any abnormal changes:

**Myocardium:** About the blood vessels of the myocardium were small scars which radiate between the muscle fibers and contain an occasional small accumulation of myocytes.

The anatomic diagnosis was verrucous streptococcic aortitis of the descending portion with formation of an aneurysm; perforation of the aneurysm into the pericardial sac and tamponade of the pericardial sac by the hemorrhage; compression atelectasis of the left lung and recent hemorrhagic infarct in the apex of the left lung; loose, fibrous adhesions about the left lung; compensatory emphysema of the right lung; cloudy swelling and anemia of the liver; hyperplasia of the lymph follicles of the spleen; slight congestion of the kidneys; ascites and left hydrothorax.

## DISCUSSION

The changes in the adventitia and media of the aorta, in the course of rheumatic infection, have been much emphasized to the neglect of the important changes that may involve the intima. Few references to the occurrence of verrucous lesions in the intima of the aorta and large arteries are present in the literature. Heydloff<sup>12</sup> described verrucae in the innominate and carotid arteries. In one case, that of Barbacci,<sup>13</sup> these lesions begin 1 cm. above the sinus of Valsalva and histologically were not unlike the organizing verrucae of rheumatic endocarditis. Bacteria could not be demonstrated in them. The heart was normal.

It is quite possible that some of the cases were rheumatic in origin though no reference is made to this possibility by any of the authors. Neither are the histologic descriptions sufficiently detailed to justify any definite conclusions. It must be remembered, however, that these papers antedated the recognition of the specificity of the lesions in rheumatic cardiac disease. While many of the older writers, particularly the French authors, have ascribed to the "rheumatic virus" an important place in the causation of arterial disease, the connection was based upon clinical inference rather than histologic specificity.

Pappenheimer and von Glahn<sup>16</sup> recognized the possibility of invasion of the aorta by way of the lumen, as did also Perla and Deutch<sup>21</sup> and Kugel and Epstein.<sup>24</sup> Its importance, however, as the primary port of entrance has not been sufficiently stressed. Where mention of this possibility is made, it is considered unlikely for want of sufficient evidence.

In a consideration of the various types of inflammatory lesions described in the aorta in rheumatic fever, three groups may be distinguished. First, invasion by means of the vasa vasorum with involvement of the adventitia alone; more extensive inflammatory reaction may lead to involvement of the media or even to the intima and thus severe damage to all three layers. Should the acute reaction, described as the forerunner of the flame-shaped scars (Pappenheimer and von Glahn<sup>16</sup>), be a little more extensive or should several of these lesions be localized in one area, the resulting healing process may terminate in a gross scar; or should the reaction take place within a wall of the vasa vasorum with a subsequent thrombosis of that vessel, gross scarring may result. The rarity of these gross lesions in the aorta may be attributed either to the relatively slight involvement of the aorta in rheumatic fever, or to the belief that because the scars in the media resemble a process produced by syphilis, it is a syphilitic process. Aside from the history, the clinical picture, the serologic test, and the observations in other parts of the body, there are definite histologic differences between the scars of the media in syphilis and the scars found in cases in which they are believed to be due to rheumatic fever (Gray and Aitken<sup>21</sup>). Should the resultant scars or the degenerative and inflammatory process preceding these scars weaken the media to such an extent as to be unable to support the burden of the passing blood stream, a break results with a subsequent stretching of the remaining portions of the wall of the aorta, and an aneurysm forms.

Second, we may have invasion of the aorta by direct extension from an adjacent lesion (Pappenheimer and von Glahn<sup>17</sup>).

Third, we may have invasion from the lumen with the primary port of entrance in the intima with the formation of verrucae.

In the three cases presented here, we found one type of lesion common to all, namely verrucae. In Case 3 streptococci were demonstrated. In one case an aneurysm was present and in another, a rupture of the aorta. In attempting to link up the findings in these cases, we are struck with the common feature of all. The histologic picture of the changes in the intima are very similar to the changes observed in the formation of the nodules throughout the body in the course of rheumatic fever. Klinge<sup>35</sup> looks upon the widespread connective tissue damages as of close morphologic relationship. According to him, the first and essentially evident change consists, not in the cellular nodules, which are already developed, but as a degenerative change of the ground substance of the connective tissue. In a circumscribed area at the point of attack of the infecting agent, a fibrinoid swelling of the intima takes place; this is the first reaction. This stage, which Klinge<sup>35</sup> calls the early rheumatic infiltration (*rheumatisches Frühinfiltrat*), is found in the first fourteen days of the affection. It is characterized by an edema of the connective tissue and in the single bundles of fibrils; wax-like refractive masses are seen with the fibrils failing to stain with ordinary methods. When the damage is very severe, necrosis results.

In the light of these findings, we can interpret the formation of the verrucae as follows: first, there is a fibrinoid swelling, in a circumscribed area of the intima, at the point of attack of the infecting agent. The fibrinoid swelling progresses to such an extent that it rises above the surface of the unaffected intima. Later, it is followed by a proliferation of the cells of the intima so that a definite firm nodule results. The proliferating cells are chiefly of fibrocyte type with a varying amount of small round cells. The affection may either subside leaving in its wake a plaque, or it may progress, when regressive changes in the form of necrosis become more prominent. The inflammatory and necrotic changes may advance into the deeper layers breaking through the internal elastic membrane and involving also the media. The destruction in the media may be so extensive as to cause a break in the continuity of the wall of the vessel under the force of the blood pressure. Thus verrucous aortitis may lead to a spontaneous rupture of the aorta with subsequent death from hemorrhage. It may also lead to the formation of an aneurysm due to a break in the continuity of the wall of the vessel sufficiently limited to allow the other parts of the wall to become stretched and transformed into a sac. This sac may later rupture, as for instance in our case; in which the aneurysm broke into the pericardial sac. Invasion by granulation tissue from the outside may also lead to the formation of an aneurysm by disrupting and weakening the muscle and elastic fibers of the media, as was previously pointed out.

These verrucous lesions should not be confused with thrombi since they are the result of productive and regressive changes of the intima. There is no thrombus formation primarily. It is not a thromboendarteritis. In their morphology, the vascular verrucae are very similar to, if not identical with, the valvular verrucae.

The question will arise as to the specificity of the verrucous aortic lesions. In Case 1, the myocardium revealed nodular accumulations of large cells located

near the larger blood vessels. They presented the characteristic picture of Aschoff nodules. In the first case, therefore, we can definitely state that the verrucous aortitis is on a rheumatic basis. In Case 2, there were severe alterations of some of the muscle fibers of the myocardium. Between some of the muscle fibers and around the adjacent larger vessels, there were accumulations of polymorphonuclear leucocytes. Thus there was present in this case an acute myocarditis, but not specific of rheumatic fever. In this case also, there was a 2+ positive Kahn reaction on the postmortem blood, and histologically there was found evidence of a typical focal syphilitic mesaortitis. The syphilitic aortitis, however, showed no topographic or morphologic relationship to the verrucous lesion on the intima of the aorta. In the third case, there were present small scars about the blood vessels of the myocardium, which contained an occasional small accumulation of myocytes. These scars may, perhaps, have been the result of rheumatic fever, but nothing was found to substantiate this diagnosis. In Case 3 also, cocci were demonstrated. Whether these cocci have any definite relation to rheumatic fever, we are not prepared here to say. But we can, however, state that streptococci may cause lesions very similar to those observed in proved cases of rheumatic fever.

## SUMMARY

Three cases are presented which have one common feature, namely, a verrucous aortitis. In one case, which was associated with a stenosis of the isthmus, the verrucous aortitis had caused a spontaneous rupture of the aorta in an eleven-year-old child. In another, a four-year-old child, an aneurysm of the aorta developed on the basis of it and ruptured into the pericardial sac. Streptococci were demonstrated in this case.

The formation of the verrucae is explained on the basis of a fibrinoid swelling and necrosis of the ground substance of the intima with proliferation of the adjacent fibrocytes. The rupture and aneurysm are explained on the basis of necrosis destroying the internal elastic membrane with subsequent weakening of the media. The nonspecificity of the verrucous lesion of the intima of the aorta is pointed out.

# CORYNEBACTERIUM DIPHTHERIAE GRAVIS FOUND IN MARYLAND\*

ONA R. WHITLEY, A.B., BALTIMORE, MD.

IN A study of *C. diphtheriae* and similar organisms in Maryland, an organism resembling *C. diphtheriae gravis* described by Anderson, Happold, McLeod, and Thomson<sup>1</sup> was recently isolated. This organism was obtained from throat and nose cultures in three contact cases in a family in which there was a fatal case.

The bacteriologic findings are given in the following description.

*Colony Morphology.*—The colonies on tellurite agar in 48 hours are flatter and more spreading than those of the ordinary colonies of *C. diphtheriae*. The colonies are also dull grayish black (nonglistening) as contrasted with the glistening black colonies of the ordinary type. They have radial lines which are noticeable at 48 hours and are still more evident later. This is contrasted with the smooth colony of the ordinary type with its more pronounced concentric ridges.

*Morphology of Organism.*—Grown on Löffler's medium, the organism lacks the slenderness usually associated with the ordinary type and, when stained with methylene blue, the areas which usually stain intensely in the ordinary types take the stain less heavily, so that the general impression is that of a lighter blue. Also few or no metachromatic granules are found. When it is grown on infusion agar slants, the morphology is even more strikingly different from that of the ordinary type. The organism then is much shorter resembling *C. xerosis*. The staining is even and lighter blue, and there is an absence of granules.

*Pellicle Formation.*—In infusion broth, a pellicle forms after an incubation period of 24 hours. This is easily visible if the tubes are held up to the light and viewed from below, diagonally. There is a granular deposit, and the broth remains clear. After 48 hours' incubation, these observations are decidedly pronounced. The ordinary type shows little or no pellicle, a moderately granular formation and a definite turbidity of the broth.

*Hemolytic Action.*—There is very little hemolysis in poured blood agar plates after 24 hours' incubation as contrasted with a definite clear zone produced by the ordinary type of *C. diphtheriae*, but on further incubation, definite hemolysis is produced.

*Fermentation Reactions.*—Acid is produced from dextrose, dextrin, maltose, starch, and glycogen in nutrient broth medium. The ordinary strains do not produce acid from starch or glycogen. Acid is not produced from sucrose.

*Virulence.*—Virulence was tested intradermally by administering from 0.1 to 0.15 c.c. of suspension of a 24-hour-old growth from a Löffler slant in 5 c.c. of normal salt solution. Three-hundred-gram guinea pigs were used. The con-

\*This report represents part of a thesis study on *C. diphtheriae*. The work was done in the Bureau of Bacteriology, Maryland State Department of Health, and the Department of Bacteriology of The Johns Hopkins School of Hygiene and Public Health.

Received for publication, August 24, 1933.

trol guinea pig received 500 units of diphtheria antitoxin 24 hours previous to the time both control and test guinea pigs were inoculated. A very marked reaction occurred in 24 hours in the test guinea pig while little or no reaction was noted in the control animal. A zone of erythema and edema about an inch to an inch and a quarter was produced. Test guinea pigs all died in from 48 to 72 hours. Autopsy revealed primarily congested and very hemorrhagic suprarenals with considerable serous fluid in the pleural and pericardial cavities.

The differences observed in the above described organism are probably due to dissociation of the ordinary type of *C. diphtheriae*. The organism is apparently in the "rough" phase.

### THE SEDIMENTATION REACTION IN THE NEWBORN\*

SAMUEL L. ELLENBERG, M.D., NEW YORK, N. Y.

---

SINCE 1918 when the sedimentation speed of the erythrocytes was first popularized by Fahraeus, there has gradually grown up a literature relating to this phenomenon, which has now reached considerable proportions. This in the main has been due to the intensive efforts of clinicians and laboratory workers to make use of this characteristic of the red blood cells as a diagnostic and prognostic agent in practically all the conditions which go to make up the field of medicine in its broadest sense. For the most part this work has been confined to adults and it is only within a relatively recent interval that the stimulus for investigative work has been transmitted over to the pediatric field.

A review of the literature quickly impresses one with the fact that a great number of methods have been evolved to obtain the sedimentation speed of erythrocytes. It is because of this variety of methods and the different terms employed in expressing the results that the reader is hard put to compare the sedimentation values as obtained by different authors and is forced to content himself with the conclusions of the author that the sedimentation reaction is normal, increased or decreased in certain conditions, pathologic or otherwise. This lack of standardization may perhaps account for the conflicting statements, as to the sedimentation reaction in normal individuals and in various diseases, appearing in the literature and undoubtedly impairs the value of the test.

Some confusion exists as to the speed of sedimentation of the erythrocytes of the newborn for Nadolny considered the sedimentation reaction to be slowest at the age of two months while György noted the contrary, claiming that

---

\*From the Maternity Service of Lincoln Hospital.  
Received for publication, August 28, 1933.

infants over one month showed a faster sedimentation than adults whereas infants under one month showed a definite slowing in the settling of the red blood cells.

The present work was undertaken to investigate the sedimentation reaction in the newborn by the method introduced by Linzenmeir, a method which the author had employed in the study of normal and pathologic conditions in the adult. Normal infants, born of relatively normal parents, with a normal birth history were selected as the subjects of the investigation.

#### METHOD

Owing to the technical difficulty of obtaining blood from the antecubital vein of the newborn, the superior longitudinal sinus was selected as the uniform site of obtaining the blood from these infants rather than resorting to any micromethod, it being the purpose of this investigation to obtain the sedimentation reaction values in the newborn by a standard method commonly used for adults, namely, the Linzenmeir macromethod.

The infant was securely mummified on to a padded wooden board roughly corresponding to the size of the child, leaving the head as the only movable part of the infant's body. During the act of drawing blood, this part was firmly held by an assistant effectively preventing any movement of the head. The region of the anterior fontanel was made aseptically clean with iodine and alcohol, and a needle with a 2 c.c. syringe attached containing 0.4 c.c. of 5 per cent sodium citrate was inserted into the longitudinal sinus and blood drawn into the barrel of the syringe up to the 2 c.c. mark. The needle used was  $\frac{3}{4}$  of an inch long, 22 gauge and was short bevelled. The balance of the test was carried out in the usual manner of the Linzenmeir method, the time being noted when the erythrocytes reached the 18 mm. mark.

The test was carried out on infants corresponding in age to the various days of the neonatal period.

TABLE I

| NAME       | AGE IN DAYS | SEDIMENTATION TIME<br>IN HOURS |
|------------|-------------|--------------------------------|
| Baby De L. | 2           | 18                             |

| Baby K     | 10          | 12                             |

#### COMMENT

The vena puncture of the superior sagittal sinus to obtain blood for the sedimentation tests may be open to question by some because of the possibility of damage to the substance of the brain, the formation of a blood clot, etc., but

in careful hands it is a safe method. None of the infants used as subjects in this investigation showed evidence of any trauma during the period of observation. It should, of course, be mentioned that directly following the removal of the needle pressure should be exerted over the puncture site to avoid extravasation of blood or clot formation.

With the closure of the anterior fontanel, the difficulties of obtaining blood in infants is increased unless they happen to present some veins sufficiently prominent to permit successful puncture. Therefore, it is natural that a number of micromethods should have been introduced to permit the use of small amounts of blood, not necessarily obtained from a vein, in the sedimentation test. Linzenmeir and Raunert<sup>3</sup> in 1924 reported a micromethod. One drop of blood is obtained from the lobe of the ear or tip of the finger. A capillary tube of 1 mm. width with a dilated reservoir and the upper end supplied with a thick-walled rubber tubing is filled to a certain mark with 5 per cent sodium citrate, and then the blood is aspirated to another mark so that a ratio of 1:4 is obtained. The blood is mixed in the dilated part of the tube and is placed in a rack and sealed with a rubber plate. The sedimentation time is read as in the macromethod.

Numerous other micromethods have been reported in the literature since then by Langer and Schmidt,<sup>4</sup> Cutler,<sup>7</sup> Poindecker,<sup>6</sup> Haselhorst,<sup>5</sup> Kowarski,<sup>8</sup> Ackerman,<sup>9</sup> and others, but all of them depend upon the securing of blood by means of some type of capillary tube. It is generally felt that the micromethod, although slightly less reliable than the macromethod, nevertheless gives sufficiently good clinical results to be of value especially where blood cannot be easily obtained from a vein, as often happens in infants and obese individuals. Investigation has shown that a capillary tube less than 1 mm. in diameter leads to irregular results. Kowarski also calls attention to the fact that blood from the tip of the finger settles somewhat faster than venous blood. This difference can be compensated for by changing the quantitative proportion of citrate solution to the blood, thus, Kowarski uses a dilution of 1:2.5.

#### DISCUSSION

According to the results obtained in this investigation, the sedimentation time in the normal newborn infant seems to range between seven and twenty-three hours, with the average sedimentation speed for the entire neonatal period being about fifteen hours as compared to the two hours considered to be normal in adults. There is also reflected a tendency for the sedimentation reaction to become less prolonged as the infant grows older.

Silzer<sup>11</sup> in a study of the sedimentation speed of red blood cells from the umbilical vein of 800 infants noted that 91.75 per cent of the cases showed a sedimentation time over twenty-four hours; 4.25 per cent showed sedimentation in from twelve to twenty-four hours; 3.8 per cent in from one to twelve hours and  $\frac{1}{2}$  per cent showed sedimentation in from thirty to sixty minutes. That the blood fibrinogen is probably the most important factor in the prolongation of the sedimentation reaction in infants is suggested by the work of Bruchsaler<sup>12</sup> who studied the relative sedimentation reaction and blood fibrino-

gen in infants and pregnant women and found that the maternal blood showed from 250 to 500 units of fibrinogen while the blood of the newborn infants contained from 64 to 125 units.

#### CONCLUSIONS

1. The speed of sedimentation of the erythrocytes in the newborn is considerably prolonged.
2. There is a tendency for the sedimentation reaction to be less retarded as the infant becomes older.
3. The use of the superior longitudinal sinus as a source of obtaining blood for the study of the sedimentation speed in the newborn is discussed.

## OBSERVATIONS ON THE VASCULAR RESPONSE TO DRAINAGE OF ASCITES\*

W. A. BRAMS, M.D., AND J. S. GOLDEN, M.D., CHICAGO, ILL.

IT HAS been observed that venous pressure may fall after excessive abdominal distention has been released. Plumier,<sup>1</sup> in a series of animal experiments, found a drop in the femoral vein pressure after release of fluid previously injected into the peritoneal cavity. Villaret and Saint-Girons<sup>2</sup> noted a temporary fall in venous pressure after ascites was removed from patients with portal cirrhosis. Brams, Katz, and Kohn<sup>3</sup> noted a marked fall in pressure in the femoral vein in animal experiments after abrupt release of abdominal distention. On the other hand, the pressure in the external jugular changed in only a few instances, the fall being much less than in the femoral vein. The carotid pressure in these experiments varied on abrupt release of abdominal distention; a fall, either transient or prolonged, occurred in about two-thirds of the experiments, and a rise was present in the remainder.

The present research was undertaken (a) to study the circulatory responses *during* the removal of ascitic fluid in patients with portal cirrhosis and chronic ascites, and (b) to compare the results of such gradual release of abdominal distention in these patients with the effects of more abrupt release in animal experiments.

The direct method of determining venous pressure was used. A hollow needle was inserted into the median basilic vein and connected with a manometer by suitable rubber tubing. The entire system was filled with 3 per cent sterile citrate solution from a reservoir. A little citrate solution was permitted to flow into the vein through the needle every few minutes in order to prevent clotting. Compression of the veins of the arm was prevented by adducting the extremity. Patency of the needle was tested before and after each reading of venous pressure. Sufficient time was allowed in all instances for stabilization of the level of the citrate solution in the manometer. The level of the right auricle was marked in the fourth right interspace at the junction of the middle and anterior thirds of the thorax and this point was used as the zero level on the manometer. This level was determined before each reading in order to prevent errors due to change in position of the patient during the course of the drainage.

Ten patients with chronic ascites of marked degree due to portal cirrhosis were selected for this study. Three of the patients were in the recumbent position and 7 were sitting during the drainage. Paracentesis was performed in the hypogastrium with a large trocar under aseptic precautions and after a preliminary local anesthesia. A long rubber tube was attached to the trocar in

\*From Departments of Physiology and Pharmacology, Northwestern Medical School, Medical Department, Cook County Hospital, and the Heart Station, Michael Reese Hospital, Chicago. Received for publication, August 30, 1933.

Aided by the Frederick K. Babson Fund of the Michael Reese Hospital.

order to siphon the ascitic fluid into a receptacle resting on the floor. The fluid was removed in stages, a liter at each stage in 8 experiments and in larger quantities in the other two. Venous pressure, systolic and diastolic arterial pressure, and pulse rate were noted at each stage. Respirations and the general condition of the patient were also closely observed in all instances.

The control venous pressure was normal or slightly elevated in 9 of the patients and low in one. This does not agree with Villaret and Saint-Girons<sup>2</sup> who reported a low venous pressure in all their patients with portal cirrhosis.

| 18000                             | 40                             | 120/96                      | 120                         |

\*Five minutes elapsed between removal of each 1000 c.c.

The changes in Case 6 are typical of those which occurred in all instances and are shown in Table I. An early fall in venous pressure occurred in all 8 patients in whom determinations were made after the removal of each 1,000 c.c. of ascitic fluid. In four of these the lower level of venous pressure was maintained, while in the remaining 4, a further fall occurred as more fluid was withdrawn. In all of the patients the venous pressure was lower at the end of the drainage than at the beginning.

The systolic arterial blood pressure fell in all but one of the patients, the drop varying from 4 to 34 mm. of mercury. This is in contrast to the variable results noted after abrupt release of abdominal distention in animals.<sup>3</sup> The diastolic blood pressure fell in all instances, the decrease varying from 4 to 32 mm. of mercury. The arterial blood pressure, like the venous pressure, began to fall early in the experiment. Faintness occurred in one instance where the systolic blood pressure fell from 94 to 60 mm. of mercury and the diastolic, from 76 to 54. The venous pressure in his patient had been falling gradually from the beginning, from 80 to 54 mm. of citrate solution. At the

time the patient complained of vertigo, the venous pressure fell abruptly from 54 to 35 mm. of citrate solution. The patient recovered in a few minutes after which the systolic blood pressure rose to 74 and the diastolic to 54 mm. of mercury. The venous pressure also rose at this point to 43 mm. of citrate solution. The fall in arterial pressure in this patient occurred before the venous pressure dropped; a finding in accord with that reported by Brams, Katz and Kohn<sup>3</sup> in animal experiments.

The pulse rate was slower in 6 patients at the end of the experiment and unchanged in 4. It is interesting to note that no increase in pulse rate occurred during the period of faintness in the patient described above in detail.

The early fall in venous pressure appears to be due chiefly to improvement in respiratory excursion. The respirations became definitely deeper after some ascitic fluid was removed. A further fall in venous pressure occurred in these patients when they were instructed to breathe more deeply. A similar fall in venous pressure was reported by Meyer and Middleton<sup>4</sup> during the hyperpneic stage of Cheyne-Stokes respiration and by Kroetz<sup>5</sup> after continuous deep breathing. The mechanism for the venous pressure drop might be the increased aspiration of blood into the thorax accompanying the greater respiratory excursion.

The fall in arterial blood pressure and pulse rate is more difficult to explain. A number of factors were pointed out in the discussion of the results obtained in animal experiments; the most likely factors being (1) decrease in peripheral resistance due to reduction of compression of the abdominal aorta, arterioles, and capillaries and (2) reflexes via the splanchnic nerves.

The clinical significance of a fall in blood pressure is important, as a marked drop such as occurred in some of our patients may lead to collapse. In a patient with a normal blood pressure and a quickly adjusting vasomotor reaction, no harm may result but even a small blood pressure drop may be serious if the blood pressure is low to begin with. A subsequent study of all 10 cases showed that the only patient in whom collapse occurred was in an instance where the blood pressure before tapping was 94/78. Further observations are necessary to determine whether such a low blood pressure warrants caution in the removal of ascites. Another patient (Case 3) went into collapse on two preceding occasions when the fluid was removed while in a sitting posture. His systolic blood pressure was 142 mm. of mercury and the diastolic was 90. Removal of the same quantity of ascitic fluid at the same rate as on the previous occasions resulted in no untoward effects when drainage was performed in the supine position. It is possible that this patient with a normal blood pressure is an example of failure of the vasomotor system to adapt itself sufficiently to the changes induced by removal of ascites. In any event, it is suggested that the patient be placed in a recumbent position in all cases where ascites is to be drained, and a hypodermic syringe of adrenalin be available.

#### SUMMARY

1. The effect of draining off abdominal fluid on the venous pressure, systolic and diastolic arterial blood pressure and pulse rate was studied in 10 patients with portal cirrhosis and chronic ascites.

2. The venous pressure began to fall early during the drainage, and in four instances continued as more fluid was removed. The venous pressure at the end of the drainage was lower in every instance than before tapping was begun.

3. Systolic and diastolic arterial pressures fell while the fluid was being removed. A fall in blood pressure was associated with faintness in one patient whose pressure was low before the procedure was begun. A similar fall in other cases with previously normal blood pressure was not associated with such untoward symptoms.

## PIGMENT STUDIES<sup>2</sup>

### I. ON A BROWN SKIN-ADRENALIN COLOR REACTION

CLARENCE QUINAN, M.D., SAN FRANCISCO, CALIF.

MEIROWSKY<sup>1</sup> seems to have been first to call attention to the fact that a melanin-like substance forms itself when an extract of human skin is heated in the presence of adrenalin. His original experiment was made with a mixture that consisted of "suprarenin (1:1,000)" one part, extract of preputial skin one part, and water one part. After this preparation had been incubated for twenty-four hours at 56° C., he noted that its color had changed from a light yellow to an intense grayish black. More recently<sup>2</sup> it has been shown that sections of whole skin exhibit a like reaction.

Two questions about this striking phenomenon still await elucidation—one concerns the chemical composition of the pigment substance itself and the other, its mode of formation.

With respect to the second query—the only one considered here—the view seems to prevail very generally that the pigment is produced in some way through the activity of an oxidizing ferment present only in living epithelial cells. Indeed, having shown experimentally that sections of human skin treated with a 1 to 2 per cent aqueous solution of 3, 4-dioxyphenylalanin exhibit a similar color change. Bloch<sup>3</sup> insists that the brownish substance is formed through the agency of a specific intracellular ferment, the so-called

<sup>2</sup>Received for publication, August 30, 1933.

dopa oxydase. This ferment is said to be thermolabile<sup>3</sup> and to be rendered inactive, if not actually destroyed, at a temperature of 57° C.

The work herein reported was undertaken in order to ascertain, in regard to the factor of temperature whether sections of human skin would display a peculiarity previously noted in experiments with a finely powdered preparation of ricinus lipase. Concerning this peculiarity, it was found constantly on incubating a small quantity of the lipase material in a dilute solution of adrenalin at 45° C. that in the course of a week or two the color of the precipitated powder gradually changed from white to brownish black. But, on the other hand, it was also noted constantly that this color reaction took place with equal, if not slighter, intensity when such experiments were repeated with a lipase powder previously sterilized by heating it in steam for half an hour at 100° C. To check this finding by means of another tissue, similar experiments were made with bits of human skin, using as test objects small squares of it that measured about 5 mm. on a side.

#### MATERIAL AND TECHNIC

The working material used was obtained, as needed, from 26 selected seemingly normal, coroner's subjects. Qualitative details about this material may be dispensed with, as the various specimens of skin tested did not seem to differ from one another significantly as regards their pigment-forming capabilities. It should be stated, however, that care was taken to select skin that was both white in color and free from coarse hairs. Each specimen was prepared for use by paring away as much as possible of the subcutaneous fat. This having been done, and the skin having been washed clean in running tap water and dried with a cloth, it was then cut into squares of the proper size.

It was found convenient to make the experiments in small test tubes (1 cm. in diameter). The preparation used routinely consisted of a single test square and 4 c.c. of an adrenalin solution made by diluting Parke, Davis and Company's adrenalin solution (1:1,000) with freshly boiled distilled water in the proportion of 1 to 5. Whether fresh or steamed, the squares were tested in three ways, namely, in an open tube, in another sealed by a layer of heavy mineral oil and in a third tube sealed by fusing the open end over a Bunsen burner. Toluene was added only to the unsealed preparations. The tests were set up in parallel series. In one of these the skin was tested in its original, fresh state, in the other, after it had been heated for half an hour in moist

TABLE I\*  
PIGMENT FORMATION IN HYDROLYZING SKIN-ADRENALIN SYSTEMS

| Squares of steamed skin | 58           | 58                     | 67                     |

\*Shows average time interval, in hours, before appearance of a brown substance in preparations made, respectively, with squares of living skin and squares of devitalized skin. Values shown are based on data noted in parallel series of experiments with skin specimens obtained from 26 coroner's subjects. Incubation temperature 45° C.

steam at 100° C. Satisfactory results were obtained by incubating the preparations at a constant temperature of 45° C.

#### RESULTS

When such preparations were placed in the incubator and observed from day to day, in the course of from twenty-four to seventy-two hours it was noted that the adrenalin solution became faintly pink in color; and that immediately after this coloring matter made its appearance—never before—the skin squares began to turn brown. This change was at first barely perceptible as an extremely pale shade of brown. But the reaction being a progressive one, often in the course of from six to ten days, the squares became almost black in color. There seemed to be a relationship of some sort between the rate of formation of the brown pigment and the color of the supernatant adrenalin solution. For it was obvious that the brown material was produced but slowly while the adrenalin solution was pale pink in color, at a more rapid rate while it exhibited a clear, rose pink shade, and most rapidly when its color had become reddish brown. These color changes occurred earlier and seemed to be somewhat more pronounced in the preparations made with squares of devitalized skin than in those made with squares of living skin; the average values obtained as regards the time of onset of the brown staining effect were, respectively, fifty-eight hours and seventy-three hours (Table I). Formation of the brown dyestuff took place in both of the preparations from which air was excluded. But on the whole it formed more slowly in the preparations sealed by fusion than in those sealed by a layer of mineral oil.

In numerous collateral series of experiments it was noted, constantly, that the addition of 1 per cent by weight of sodium chloride to a preparation caused the square—whether a heated or an unheated one—to turn brown within twenty-four hours and to exhibit a maximum grade of pigmentation within a period of four days.

Control squares of skin were incubated in distilled water at 45° C. Without exception, after an incubation period of two weeks each square remained as perfectly white as it had been when in the fresh state.

#### SUMMARY

1. Experimental data are presented which show that bits of human skin become dark brown in color on being incubated in a dilute solution of adrenalin.
2. The results obtained seem to show conclusively that the brown pigment forms itself in the absence of any organized ferment.

The author wishes to thank Mr. Paul C. Greene for valuable technical assistance rendered during the course of this study.

## PIGMENT STUDIES\*

### II. ON THE IMPORTANCE OF HYDROLYZED ADRENALIN AS A TISSUE STAIN

CLARENCE QUINAN, M.D., SAN FRANCISCO, CALIF.

IN THE preceding study it was found with respect to two organic substances, one of vegetable, the other of animal origin, that they gradually became almost black in color if they were incubated for some time at 45° C. in a hydrolyzing solution of adrenalin; and that this phenomenon occurred whether these substances were tested in the fresh state or after they had been heated in live steam for half an hour at 100° C. The materials tested were small quantities of defatted castor bean meal and bits of human skin.

Apparently, the conditions under which the experiments had been made were such as to preclude the possibility that the melanin-like pigment had formed itself through the agency of an organized ferment. It seemed probable, nevertheless, that the process of pigment formation was essentially a catalytic one; and that the color change noted took place because of the fact that the solution contained some cleavage product of adrenalin which acted upon the tissues and dyed them brown. In other words, the evidence seemed to indicate that the solution of hydrolyzed adrenalin acted simply as a non-specific stain. As it seemed worth while to secure, if possible, some data on this point, many series of experiments were made with suitable test objects representative of various cellular structures. The results obtained show that under proper conditions a hydrolyzing solution of adrenalin is capable of imparting an intense brownish black color to a number of organic substances. Since it does not appear to be generally known that such a solution has tinctorial properties, this paper gives a brief account of the staining experiments.

#### MATERIAL

Four kinds of material were tested: white holly, normal human skin, normal human red bone marrow, and blood obtained from a patient afflicted with myelogenous leucemia.

The white holly was purchased from a cabinetmaker. It consisted of small sheets of veneering, about 1 mm. in thickness and perfectly "dressed" on both surfaces. Pieces of this wood 1 cm. square were used in the experiments. The specimens of skin tested, as well as those of bone marrow, were obtained, as needed, from carefully selected coroner's subjects. The tissues were prepared for use as follows: Each skin specimen, in the usual manner, was first hardened in 10 per cent formaldehyde and then embedded in paraffin and sectioned. The staining tests were made with sections attached to glass slides by means of an albumin fixative. In the experiments made, respectively, with red bone marrow and leucemic blood, the usual smear preparations were used. Both were fixed in absolute alcohol.

\*Received for publication, August 30, 1933.

## TECHNIC

1. *Preparation of the Staining Solution.*—Into a cylindric specimen tube 3 cm. by 8 cm. in size, 3 c.c. of Parke, Davis and Company's adrenalin solution (1:1,000) and 7 c.c. of freshly boiled distilled water were measured by means of a pipette and then, to serve as a catalytic agent, a bit of human skin 5 mm. square—previously steamed for half an hour at  $100^{\circ}$  C.—was dropped into the tube. To prevent loss by evaporation the tube was provided with a tightly fitting stopper. The preparation then was incubated at  $45^{\circ}$  C. and observed from day to day with reference to the appearance of two color reactions—one in the supernatant solution, the other in the little piece of tissue. As a rule, in the course of from one to three days, the solution gradually became deep rose pink in color while, toward the end of that period, the bit of skin began to exhibit a very pale brownish discoloration. When both of these color changes were visible, the solution was ready for use.

Fig. 1.—Squares of white holly stained in a solution of hydrolyzing adrenalin. One and three are squares of the wood in its natural, unheated state. Two and four are squares steamed for half an hour at  $100^{\circ}$  C. before they were tested. Five is the control strip. Incubation period was six days. Temperature  $45^{\circ}$  C. Note that the heated squares are darker in color than the unheated ones.

2. *The Staining Procedure.*—Slide preparations of the tissues to be tested were brought into the rose pink solution and then incubated at  $45^{\circ}$  C. until the desired brown staining effect developed. This usually required a period of from six to ten days. It should be mentioned that the squares of white holly were introduced into the solution edgewise and kept in a vertical position by means of suitable holder devices fashioned out of glass tubing.

## RESULTS

*White Holly*

Experimental evidence was sought especially in regard to two points: (1) Does heat modify the action of the stain in any way? (2) Is the staining process modified by the factor of concentration?

*Influence of the Heat Factor.*—Method: Two pieces of white holly were used in each experiment, namely, a square of the wood in its natural, unheated state, and a square that had been steamed for half an hour at  $100^{\circ}$  C.

Results: On removing the squares from the solution after the proper time interval, it was found constantly (1) that both of the squares had changed in color from white to brown; (2) that the heated square was several shades darker in color than the unheated one. (See Fig. 1.)

*Influence of the Concentration Factor.*—Method: Proceeding in the manner already described and using in each instance a bit of steamed skin as the catalyst, a series of five staining solutions, regularly graded in concentration according to the amount of adrenalin present in each one, were made ready for use in the small cylindric containers. By volume these preparations contained, respectively, 20, 40, 60, 80, and 100 per cent of commercial adrenalin solution (1:1,000). Having then placed in each container a square of unheated white holly to serve as a test object, the preparations were incubated at 45° C. for the usual length of time.

Fig. 2.—Showing influence of the concentration factor. The unheated squares, one to five were stained simultaneously in solutions that contained, respectively, 20, 40, 60, 80, and 100 per cent of adrenalin (1:1000). Incubation period six days. Temperature 45° C.

Results: In a typical experiment, after the lapse of six days it was found that the set of squares displayed the color changes of graded intensity shown in Fig. 2. The tone range was from pale brown to brownish black. The differences between individual squares of a series, as regards the relative depth of the staining effect, were rendered remarkable by a particular circumstance; for it will be noted that the grain of the wood stands out more or less conspicuously in the first three squares, stained in the weaker solutions, while the remaining two squares appear to be uniformly black in color.

### Skin

Hope was entertained that suitable tests with thin sections of skin would serve to explain a peculiarity in regard to the distribution of the brown dye-stuff previously noted in the experiments with whole skin. For on examining bits of blackened skin removed from old testing solutions, it had been observed invariably that the brownish black staining effect was most pronounced at or near the free epithelial surface of the specimen while, in striking contrast, the deeper, subcutaneous tissues showed much lighter degrees of discoloration. Since it seemed probable that thin sections of skin would stain more

evenly, numerous slide preparations were incubated in the staining solution until the proper color developed and then were examined under the microscope. Contrary to expectation, however, it was found in every case: (1) That the amount of the brown material present in the tissue increased in the direction from the depth toward the free surface of the section. (2) That the deep layers of the stratum corneum were so intensely stained that an average section (see Fig. 3) had the appearance of being bordered on one side by a sharply defined zone wherein the black staining effect closely resembled that observed in the experiments with white holly.

Fig. 3.—Section of normal human skin stained in hydrolyzed adrenalin for six days. ( $\times 125$ )

Comment: The foregoing observations seem to justify the inference that the depth of the brown discoloration at any given level in a stained section of skin is related in some way to a density factor. At any rate, figuratively speaking, it would appear that somewhat as the lines in a contour map indicate the pitch of a slope by their nearness to one another, so in a stained section of skin the color appears to be darkest near the surface where the cells are closely packed.

#### *Leucemic Blood and Red Bone Marrow*

Method: As it was desired to find out what staining effects, if any, would take place if representative groups of leucocytes were incubated in the adrenalin solution, simultaneous tests were made with two smear preparations—one of leucemic blood and one of bone marrow. Twenty experiments were made in all. The average time period was six days.

Results: Although the pigmentary changes observed varied considerably both in degree and extent, it was found, without a single exception, that the leucocytes exhibited brown color reactions. In a majority of the specimens the staining effects were comparatively slight in degree and were limited to the nuclei, causing these to appear as pale brown objects sharply outlined within the colorless cell bodies. But not a few other specimens were encoun-

tered (see Figs. 4 and 5), which afforded obvious proof that the brown dye had stained deeply not only the nuclei of the leucocytes but also the myelocytic granules. Therefore, having in mind the evidence previously acquired, it was inferred from these observations, (1) that the test solution contained a diffusible nonspecific pigment of unknown composition; and (2) that al-

Fig. 4.—Smear of leucemic blood stained in hydrolyzed adrenalin for six days.

Fig. 5.—Smear of human red bone marrow stained in hydrolyzed adrenalin for six days.

though the conditions essential to the development of its maximum activity were undetermined, this substance stained the component tissues of the leucocytes with unequal intensity.

#### SUMMARY

1. A new method is presented for the preparation of a rose pink solution of hydrolyzed adrenalin.
2. Under suitable conditions this solution imparts a deep brown or brownish black color to various organic substances.

3. The brown dye appears to be nonspecific in its action.
4. The staining effects obtained with specimens of white holly, human skin, leucemic blood and red bone marrow are described.

## CRYSTALLINE ELEMENTS IN THE STOMACH LAVAGE OF PATIENTS WITH CHOLELITHIASIS\*

HENRY A. RAFSKY, M.D., F.A.C.P., NEW YORK, N. Y.

IN A PREVIOUS paper,<sup>1</sup> certain types of crystals, present in preoperative specimens of bile, in patients with gallbladder disease, were described and compared with biliary crystals found in the scrapings of stones and bile removed from the gallbladder at operation. During the course of the above investigation, it was observed that in some patients, the duodenal tube did not pass beyond the pylorus within a period of eighteen hours. A microscopic examination of the aspirated gastric contents of these patients revealed various types of biliary crystals. It was, therefore, thought of interest to determine the frequency with which crystalline elements were found in the gastric contents of patients with gallbladder disease. For this study, 28 patients were observed.

The patients were grouped as follows: Group 1, consisted of 21 patients, in whom there was definite roentgenographic evidence of cholelithiasis. Group 2 (the control group), consisted of 7 patients who were free from gastrointestinal symptoms.

The gastric contents of all the patients were obtained by stomach lavage, because (lavage) water was found to be the best medium for the microscopic detection of biliary crystals. The gastric lavage was performed with plain tap water, preferably in the morning, on any empty stomach. A specimen of the lavage water was then collected and examined microscopically.

In Group 1, there were 21 patients. Five of these were males, and 16 females, the ages ranging from thirty-one to sixty years. Typical and atypical cholesterol crystals, carbonate crystals, and calcium bilirubinate pigment (granular and amorphous types), separately or collectively, were found in the gastric lavage of every one of the patients in this group. The crystals and pigment were present in appreciable amounts, and as follows: Cholesterol and calcium bilirubinate pigment, together in 14 patients; cholesterol and carbonate crystals together with calcium bilirubinate pigment in 3 patients (Figs. 1 and 2); cholesterol crystals alone in 2 patients; and calcium bilirubinate pigment alone in 2 patients. The cholesterol type of crystal predominated in 9 of the patients in this group. Calcium bilirubinate pigment was most abundant in

\*From The Max Einhorn Gastro-Enterological Clinic and the Surgical Division of The Lenox Hill Hospital.

Received for publication, September 5, 1933.

12 patients. The crystalline elements were found, at times, in the mucus, and, at other times, independent of the mucus. It was not necessary to centrifuge the specimens to obtain the crystals.

Fig. 1.—Mrs. K. Cholesterol and carbonate crystals; slight amount of calcium bilirubinate pigment. (Microphotograph of particle in preoperative specimen of gastric lavage.)

Fig. 2.—Mrs. F. Abundant amount of calcium bilirubinate pigment and few cholesterol and carbonate crystals. (Microphotograph of particle in preoperative specimen of gastric lavage.)

Eighteen of the patients in Group 1 were operated upon. In all of these cases, the crystalline elements observed in the lavage water, preoperatively, were found to be similar in appearance to the biliary crystals seen in the scrapings of stones or bile removed from the gallbladder at the time of operation.

Group 2 (the control group) consisted of 7 patients ranging in age from twenty-five to fifty years, all of whom were free from gastrointestinal symptoms. Four of these patients were males, and 3 were females. These patients came to the hospital for other than abdominal ailments, and, as far as could be ascertained, never complained of gastric symptoms. Microscopic examination of the stomach lavage obtained from these patients did not reveal the presence of cholesterol or carbonate crystals. In only 4 of the patients a slight amount of calcium bilirubinate pigment was found.

# COMMENTS

Cholesterol and carbonate crystals and calcium bilirubinate pigment were found, separately and collectively, in appreciable amounts, in the stomach lavage of a group of patients suffering from calculous cholecystitis. The presence of these crystalline elements in the gastric lavage was due to regurgitation of the bile and duodenal contents into the stomach. In about one-half of the patients the gastric lavage water was bile tinged, and, in the remaining patients, it was colorless.

Although biliary crystals were present in the stomach lavage in appreciable amounts, they were not, as a rule, as numerous as the crystals seen in preoperative specimens of bile of patients with cholelithiasis. When, however, the gastric lavage was performed within six hours after the onset of an attack of biliary colic, showers of crystals and an abundant amount of calcium bilirubinate pigment were found.

Carbonate crystals in the stomach lavage were dissolved by hydrochloric acid which aided in differentiating these crystals from the atypical types of cholesterol crystals. At times, starch granules in the lavage water had to be distinguished from biliary crystals. This was readily done by the addition of iodine.

Microscopic examination of the stomach lavage of the patients in the control group did not reveal any cholesterol or carbonate crystals; yet, a slight amount of calcium bilirubinate pigment was found in four of the patients. In a previous paper,<sup>1</sup> it was emphasized that a few cholesterol crystals or a small amount of calcium bilirubinate pigment, present in preoperative specimens of bile, had no pathologic significance. The presence of a slight amount of calcium bilirubinate pigment in the stomach lavage, likewise, cannot be regarded as abnormal.

The presence of biliary crystals in the stomach lavage of patients with cholelithiasis, is of some significance. However, an exact diagnostic appraisal of this finding cannot as yet be given, as this subject is still under investigation.

# CONCLUSIONS

1. A series of 21 patients with cholelithiasis, and another 7 patients (control group) free from gastrointestinal symptoms, were subjected to a microscopic examination of the gastric contents obtained by lavage.

2. The stomach lavage of the patients with calculous cholecystitis showed appreciable amounts of cholesterol and carbonate crystals and calcium bilirubinate pigment occurring separately and collectively.

3. In the control group the gastric lavage showed, in only four patients, a slight amount of calcium bilirubinate pigment, which is not regarded as abnormal.

## EFFECT OF SMOKING ON SKIN TEMPERATURE\*

HARRY J. JOHNSON, M.D., AND JAMES J. SHORT, M.D., NEW YORK, N. Y.

CONSIDERABLE investigation has been carried out during the past decade in an attempt to determine the various effects of tobacco on the human body. It has long been thought that tobacco was an important contributing etiologic factor in some of the vascular diseases, most notably thromboangiitis obliterans. Certain other conditions also have been so frequently associated with the practice of smoking that the causal connection has been considered indisputable by some authorities. In this group we can mention cardiac arrhythmias, shortness of breath, and chronic congestion of the nasopharynx.

On chemical analysis of tobacco smoke, Bogen<sup>1</sup> points out that the composition of the smoke obtained from any cigaret depends to a great extent on the manner and rate with which the cigaret is smoked. The sidestream, or the smoke from the lighted end of the cigaret, ordinarily constitutes the greater part of the actual materials given off from the combustion. This contains a low concentration of carbon monoxide with a relatively high percentage of nicotine. Smoke which has been sucked in contains an appreciable amount of carbon monoxide. This has been estimated as high as 8.3 c.c. from each gram of tobacco smoked, which is approximately the amount of tobacco in each cigaret. The amount of nicotine in the smoke sucked in is much greater than that of the sidestream. This has been estimated at from 3 mg. to 9 mg. from each gram of tobacco smoked, and 88 per cent of this is absorbed. Bogen notes also that domestic cigarets are somewhat richer in nicotine than many of the imported brands. The domestic brands average about 2.5 per cent nicotine.

Whether or not nicotine is the primary toxic agent in tobacco smoke, it is interesting to note that according to Bastedo<sup>2</sup> nicotine is rapidly absorbed from skin and mucous membranes. Its main action is a brief stimulation of the sympathetic and parasympathetic ganglia, followed by a depression. The stimulation of the ganglia results in a rise in blood pressure. The lethal dose of nicotine for an adult is about 500 mg. In addition to the nicotine and carbon monoxide, the aspirated smoke contains pyridine, aldehydes (especially furfural), and volatile oils. These are generally considered of relatively little significance.

That smoking has an effect on the cardiovascular system has long been

\*From the Department of Medicine, New York Post Graduate Medical School and Hospital.  
Received for publication, September 22, 1933.

suspected. Simici and Marco<sup>1</sup> in 1926 stated that tobacco smoke produces in both smokers and nonsmokers well-marked disturbances in the cardiovascular system. These disturbances, they consider, are characterized principally by phenomena of vasoconstriction which appear first in the visceral, and then in the peripheral vessels. They found a rise in blood pressure of 20 to 30 mm. of mercury, with an acceleration of pulse of 10 to 40 per minute. They explain this on the basis of a vasoconstriction.

Bruce Miller and Hooker<sup>4</sup> in 1909 believed that there was probably a peripheral vasoconstricting effect from smoking tobacco and demonstrated this by noting the volume changes in the arm and hand. Moschcowitz<sup>2</sup> in 1928 stated that the most probable explanation of the so-called tobacco angina is that it is due to the constrictive action of tobacco on the blood vessels of the heart.

Madoch and Coller<sup>5</sup> have more recently shown what they consider further evidence of a peripheral vasoconstriction as a result of smoking, by determining the temperature of the skin of the upper and lower extremities. In the case mentioned in their report, they found a drop of  $5.9^{\circ}$  C. in the upper extremity and  $1.5^{\circ}$  C. drop in the lower extremity while the subject smoked 3 cigars.

In the present study 34 subjects were used. An attempt was made to obtain a record of the changes in the temperature of the skin while the subjects were smoking. The region just below the nail of the third finger of the left hand was selected as the site for temperature determination. The subject's hand was placed in a comfortable position and relaxed. The instrument used for measurement was the Leeds and Northrup electric recorder. The thermocouple was fastened to the site selected and the record taken.

After a constant temperature was obtained the subject was instructed to smoke a cigaret in his accustomed manner, continuing to smoke until approximately  $\frac{3}{4}$  of the cigaret had been consumed. Several of the popular brands were used. Room temperature varied between  $63^{\circ}$  F. and  $86^{\circ}$  F. In no case did the lowest temperature reached go below room temperature during the progress of the experiment.

In Table I 26 of the subjects were habitual smokers, consuming from 15 to 30 cigarettes daily. Of these, 22 showed a drop in skin temperature averaging  $4.3^{\circ}$  F., 2 showed no change at all, and one showed an elevation of  $8^{\circ}$  F.

Four of the subjects in Table II were retested, and in each case a comparable change was noted except one, where the drop was approximately half of the original.

In the group of 8 nonsmokers, 3 showed an average drop of  $3.2^{\circ}$  F., 4 showed no change at all, and 1 showed an elevation of  $1^{\circ}$  F.

Four cases of thromboangiitis obliterans were studied, 3 of which showed an average drop of  $8^{\circ}$  F. One showed no change at all.

In practically all of the cases studied where a drop in temperature was noted, the temperature change was evident before one-half the cigaret had been consumed. The average time required to reach the lowest temperature from the beginning of smoking was fourteen minutes, with five minutes as the minimum and fifty minutes as the maximum. The time required to return to the initial temperature or higher after the low point, averaged twelve minutes with five as the minimum and twenty-five as the maximum.

In 4 cases the minimum temperature was reached and the return elevation of temperature began while the subject was still smoking.

There was apparently no relation between the number of cigarettes consumed daily by the subject and his temperature reaction.

TABLE IV  
THROMBOANGIITIS OBLITERANS

| SUBJECT | ROOM TEMP. | INITIAL TEMP. | LOWEST TEMP. | DEGREES DROP | TIME OF DROP<br>min. | RETURN TEMP. | TIME OF RETURN<br>min. |
|---------|------------|---------------|--------------|--------------|----------------------|--------------|------------------------|
| 13      | 76         | 91            | 84           | 7            | 24                   |              |                        |
| 17      | 76         | 96            | 89           | 7            | 25                   | 95           | 22                     |
| 23      | 82         | 86            | 75           | 11           | 50                   |              |                        |

In comparing the group of smokers with the nonsmokers, it will be noted that 88 per cent of the smokers showed an average drop in skin temperature of 4.3° F. In the nonsmoker group only 36 per cent showed a drop and this average was 3.2° F. Conditions were identical for both groups. It was noted, however, that the nonsmokers did not inhale. Earp<sup>7</sup> has pointed out that inhalers take 8 times as much nicotine into their systems as smokers who do not inhale. Winterstein and Aronson showed that from 2.5 per cent to 4.4 per cent of the nicotine is absorbed on smoking without inhaling and from 8.1 per cent to 17 per cent is absorbed when inhaled. When we consider that in the act of inhaling, the smoke is exposed to the mucous membranes of the nasopharynx and the lower respiratory passages, thus giving an infinitely larger surface on which the products of smoking may condense, we may expect a greater deposition and consequent absorption of nicotine and other components, than would result from simply puffing the smoke in and out of the mouth. This may be the explanation for the marked difference between the temperature changes of the smokers as compared with the nonsmokers.

In personal communication with Dr. Wright, pertaining to his work on capillary activity during active smoking, he states:

"In certain individuals we have been able to note a marked slowing and often stasis in the capillary circulation at the nailfold during the smoking of a single cigaret. This phenomenon when present can be seen after the first few deep inhalations. It has been found especially in subjects who complain of systemic symptoms from the use of tobacco."

#### COMMENT

As has been repeatedly contended during the past few decades, this work further tends to confirm the opinion that smoking does bring about a peripheral vasoconstriction, which may be a significant contributing etiologic factor in certain of the vascular disorders and particularly in thromboangiitis obliterans.

NOTE: Since this manuscript was prepared, Haggard and Greenberg<sup>8</sup> have shown that an increased blood sugar results from smoking, and they attribute this to adrenal stimulation by nicotine through the sympathetics. This has been confirmed by the present writers<sup>9</sup> who also believe that the vasoconstriction described above can probably be attributed to the same cause.

VITAMIN THERAPY IN PULMONARY TUBERCULOSIS\*

---

VI. THE EFFECT OF VIOSTEROL ON THE CARBON DIOXIDE CONTENT, THE H-10% CONCENTRATION, CHLORIDES, GLUCOSE AND UREA NITROGEN OF THE BLOOD, AND PROTEIN, CALCIUM, AND PHOSPHORUS OF THE SERUM. THE EFFECT OF PHYSIOLOGIC SALINE ON THESE CONSTITUENTS DURING THE STATE OF HYPERCALCEMIA.

---

PAUL D. CRIMM, M.D., AND J. W. STRAYER, M.D., EVANSVILLE, IND.

---

IN PREVIOUS experiments<sup>1</sup> we demonstrated the effect of viosterol on the calcium and phosphorus metabolism, and the effect of intravenous physiologic saline upon these two elements. In order to determine the effect of viosterol upon other constituents of the blood we performed simultaneously the following chemical analyses before, during, and after hypercalcemia. Likewise, the same procedures were employed in determining the effect of physiologic saline upon these constituents when administered during hypercalcemia. These analyses were performed on 15 patients who had a diagnosis of pulmonary tuberculosis, Stages II and III.

## METHODS

Serum calcium was determined by the Clark and Collip<sup>2</sup> method, modification of Kramer and Tisdall.<sup>3</sup> Phosphorus determinations were made by the method of Benedict and Theis.<sup>4</sup> McDonald's<sup>5</sup> modification of Hastings and Sendroy's<sup>6</sup> method was used in making the analyses of the P<sub>H</sub>. Carbon dioxide was determined by the volumetric method of Van Slyke;<sup>7</sup> urea nitrogen according to the method of Myers;<sup>8</sup> glucose by the micromethod of Folin;<sup>9</sup> chlorides by the method of Whitehorn;<sup>10</sup> and albumin and globulin by the method of

Grateful acknowledgment is due Miss Grace Heimann for her valuable assistance.

Wu and Ling<sup>11</sup> and Greenberg,<sup>12</sup> respectively. If the albumin determination is allowed to incubate four or five hours, very little difference in the result is obtained, whereas the globulin may vary considerably after two hours.

#### THE EFFECT OF VIOSTEROL ON SERUM CALCIUM AND PHOSPHORUS

Data presented here further corroborate the earlier work<sup>13, 14</sup> with viosterol 250D\* and 10,000X.† The solution used in this experiment had a cod liver oil coefficient of 10,000, which is one hundred times stronger than 250D. The daily dose was 0.5 c.c. (20 gts.) which is the rat assay equivalent in vitamin D of 5,000 c.c. of cod liver oil. The average period of viosterol administration for this group was approximately eight days. A condition of hypercalcemia as a result of this dosage was brought about between the eighth and fifteenth days. Serum calcium concentrations averaged from 13.3 to 18.4 mg. per 100 c.c. The average normal serum calcium concentration was 11.4 mg. per 100 c.c. for the 15 cases (Table I). The average serum calcium after the period of viosterol administration was 15.2 mg., an average elevation of 3.8 mg. per 100 c.c. The average serum phosphorus concentration was 4.7 mg. per 100 c.c. before, and 4.9 mg. per 100 c.c. after the viosterol administration. It is significant to note that this concentration of phosphorus in the blood serum would have been elevated had it been determined during the first five days of viosterol administration.<sup>14</sup> However, if one determines the serum phosphorus after the serum calcium has reached a higher value, the serum phosphorus is reciprocally lower.

We have demonstrated<sup>1</sup> that physiologic saline lowers the concentration of calcium and phosphorus in the blood, and this work further verifies this specificity. Within twelve hours after the administration of between 3,000 and 5,000 c.c. of physiologic saline per individual, the serum calcium concentration dropped to 12.7 mg. per 100 c.c. (Table I), an average decrease of 2.5 mg. Serum phosphorus was decreased by physiologic saline as shown by the average of 3.7 mg. per 100 c.c., a decline of 1.2 mg.

The lowering of serum calcium and phosphorus is not due to a change in blood volume. Since determinations were made twelve hours after the administration of saline, blood volume would have returned to normal. Smith and Mendel<sup>15</sup> injected into the veins of rabbits isotonic solutions of various neutral sodium salts. The blood volume was doubled although they found that different salts were eliminated from the blood at different rates. Most of the fluid in every case passed into the tissues within five minutes without causing evident edema. If the decrease in serum calcium and phosphorus was due to dilution of the blood volume, a return to the original high concentrations would be expected after the effect of saline had passed.

#### THE EFFECT OF VIOSTEROL ON $P_H$ AND $CO_2$

The average  $P_H$  for the 15 cases was 7.39 prior to the administration of viosterol. This average is 0.02 more than the  $P_H$  of 50 normal individuals who equaled 7.37.<sup>16</sup> After viosterol the average  $P_H$  of the blood for the 15 cases was 7.41. The effect of a viosterol hypercalcemia upon the hydrogen ion concen-

\*Viosterol 10,000 X, 0.5 c.c. (20 ctt.) administered between 12:00 and 1:00 p.m.

\*Viosterol 10,000 X, 0.5 c.c. (20 gtt.) administered between eight and fifteen days. Determination made on day drug was discontinued.  
†After NaCl, determinations made twelve hours later.

tration of the blood was shown as a slight shift toward the alkaline side. Individual variations of fever may have accounted for an increased  $P_H$  in an occasional case. This is especially true after the administration of physiologic saline. This is demonstrated in Case 1,109, Table I. The average  $P_H$  for the same group after the intravenous injection of physiologic saline was 7.42. The large quantity of saline used in a short period of time had no deleterious effect on the patients outside of an occasional chill.

These data show that viosterol hypercalcemia is not accompanied by an increase in hydrogen ion concentration. In hypercalcemia produced by viosterol our data do not conform to the opinion quoted by Peters and Van Slyke,<sup>17</sup> that a lower  $P_H$  tends to mobilize the calcium in the blood stream. Bernheim<sup>18</sup> states that diffusible calcium increased with a decrease in  $P_H$ . The average for 10<sup>19</sup> of the 15 cases (5 additional ones in this report) presented in Table I shows an increase in both diffusible and nondiffusible calcium during the state of hypercalcemia when the  $P_H$  was increased. This work demonstrated that viosterol increased the nondiffusible calcium to a much greater extent than the diffusible calcium. At the same time the hydrogen ion concentration was decreased ( $P_H$  increased).

Carbon dioxide in this series of 15 cases averaged 59 volumes per cent. During the period of hypercalcemia the average carbon dioxide percentage was 61. Although this percentage is within normal limits it points to a slight increase in carbon dioxide during the state of hypercalcemia. Following the administration of physiologic saline, carbon dioxide averaged 57 volumes per cent. A decrease from 61 to 57 volumes per cent can be accounted for by fever. Collip and Backus<sup>20</sup> were the first to point out that overventilation produces an alkalosis due to washing out of carbon dioxide from the blood. This fact was later borne out by Grant and Goldman.<sup>21</sup> It was further noted by Koehler<sup>22</sup> that acute clinical fevers produce a similar picture, namely, a low  $CO_2$  and a high  $P_H$ .

#### THE EFFECT OF VIOSTEROL ON GLOBULIN AND ALBUMIN

In 10 cases (Table I) the globulin and albumin were analyzed simultaneously with the other determinations. The total protein average was found to be 6.90 gm. per 100 c.c.; globulin was 2.85 gm.; albumin was 4.05 gm. During hypercalcemia the total protein increased to 7.14 gm. per 100 c.c. This increase was due to the elevation of albumin. This is in accord with the finding of other investigators,<sup>23</sup> namely, that proteins permit serum to hold more calcium in solution. When calcium was increased by means of viosterol, it was the albumin fraction which was responsible for retention of the calcium. Globulin decreased during viosterol hypercalcemia. Following the administration of physiologic saline intravenously, the total protein decreased to 6.10 gm. per 100 c.c. Globulin and albumin decreased, the albumin more than the globulin. Further work is required to explain the mechanism by which protein is diminished following administration of intravenous physiologic saline.

#### THE EFFECT OF VIOSTEROL ON CHLORIDES, GLUCOSE AND UREA NITROGEN

The 15 cases (Table I) showed a normal average of 459 mg. of chlorides preceding the administration of viosterol. During hypercalcemia, the chlorides

averaged 428 mg. per 100 c.c. All but two cases showed a decrease in chlorides. During the intravenous administration of physiologic saline the chlorides were elevated. The average for the 15 cases was 493 mg. per 100 c.c., an increase of 65 mg. per 100 c.c. over the average during the condition of hypercalcemia, and an increase of 44 mg. per 100 c.c. over the normal average.

The average glucose concentration of the blood for the 15 cases was 102 mg. per 100 c.c. After the administration of viosterol the glucose was found to average 105 mg. per 100 c.c. Following the administration of physiologic saline, the average glucose was 105 mg. per 100 c.c. These data present a slight increase in glucose after viosterol. Physiologic saline had no effect on the glucose of the blood.

Although some cases of pulmonary tuberculosis tend to have a slightly elevated urea nitrogen, the average for this group of cases was 14 mg. per 100 c.c. During hypercalcemia, the urea nitrogen showed a tendency to increase in this series of cases. Following the administration of physiologic saline, the urea nitrogen averaged 13 mg. per 100 c.c. Sweany, Weathers and McCluskey<sup>21</sup> observed that in tuberculosis with no serious kidney lesion present, the chlorides and urea nitrogen played a reciprocal rôle. In this series when the chlorides were increased by physiologic saline, the urea nitrogen was slightly decreased.

#### SUMMARY

1. Viosterol increases the total protein, calcium, and phosphorus in the blood. The albumin fraction of the protein is increased, globulin decreased. The administration of intravenous physiologic saline decreased the total protein, calcium, and phosphorus.

2. The state of hypercalcemia produced by viosterol is not accompanied by an increased hydrogen ion concentration ( $P_H$  decreased).

3. The chloride content of the blood is slightly decreased during viosterol hypercalcemia, and the urea nitrogen is very slightly increased.

4. The carbon dioxide content and glucose are not significantly altered by the massive doses of viosterol used to produce hypercalcemia.

## CHEMOTHERAPEUTIC STUDIES WITH SODIUM RICINOLEATE (SORICIN)\*

JOHN A. KOLMER, M.D., PHILADELPHIA, PA.

ASSISTED BY MISS ANNA M. RULE AND MR. BERNARD MADDEN

**I**N CHEMOTHERAPY and especially of bacterial infections the possibility of producing chemical agents capable of inactivating or destroying toxins and related substances in the blood and other tissues has long been of engaging interest. Of course, the predominating motive of chemotherapeutic research is the production of chemical agents possessing parasiticial activity *in vivo*, but almost of equal importance is the possibility of producing compounds of detoxifying activity *in vivo* even though lacking in demonstrable parasiticial activity.

This is especially true in many of the bacterial infections not only because exogenous toxins are the chief pathogenic agents in some like diphtheria, tetanus, gangrene, scarlet fever, and erysipelas, but because bacterial products, both toxic and nontoxic, produced in the tissues during infection, would appear capable of retarding or preventing phagocytosis and preventing the activity of humoral antibodies. In the case of some bacterial infections these agents like the aggressins do not appear to be primarily toxic but are, nevertheless, pathogenic in this sense of retarding or preventing phagocytosis. In pneumococcus pneumonia for example, it would appear that the nontoxic and nonantigenic soluble substance "S" discovered by Avery and his coworkers has the faculty of neutralizing the antibodies produced by the patient and enhancing the virulence of the organisms by preventing their phagocytosis.

At the present time our main hope of combating the toxins and these nontoxic agents is by means of specific immune sera but the possibility of discovering chemical agents capable of inactivating or completely destroying them *in vivo* is of fundamental importance.

From this standpoint we have been greatly interested in sodium ricinoleate, that is, in the possibility of this compound destroying these toxic and nontoxic bacterial agents *in vivo* and especially since the investigations of Larson and his colleagues,<sup>1</sup> Sommer and Sommer,<sup>2</sup> Netter, et al.,<sup>3</sup> Dorst and Morris<sup>4</sup> and others, the literature being briefly summarized by Harris and Bunker,<sup>5</sup> have indicated that sodium ricinoleate is capable of neutralizing various bacterial toxins, phytotoxins and cobra venom in the test tube and possibly in the living animal in the case of some of them with special reference to streptococci and pneumococci.

Furthermore in chemotherapeutic research there is always the possibility of compounds inert in the test tube undergoing transformation in the living

\*From the Research Institute of Cutaneous Medicine of Philadelphia.  
Received for publication, September 14, 1933.

animal into new and more active antiparasiticideal agents. For this reason test tube bactericideal activity *in vitro* may be without curative activity in the living animal or, being extremely low in parasiticideal activity in the test tube, undergo transformation in the blood or tissues into compounds of extremely high curative activity as in the case of arsphenamine, neoarsphenamine, and other trivalent organic arsenical compounds. For these reasons test tube determinations of bactericideal activity are of most value in the case of those compounds to be used in treatment by local application, whereas in the case of those designed for parenteral administration actual tests with experimental infections in living animals are required. For example, we think it is extremely fortunate that Ehrlich and his colleagues did not have cultures of trypanosomes and *Spirocheta pallida* available in 1907, for they may have committed the error of testing their new arsenical compounds, including salvarsan, in the test tube only and finding them so low in parasiticideal activity may have neglected their administration to infected animals and thereby missed or delayed making their great discoveries. Therefore, even though we knew sodium ricinoleate to be of very low bactericideal activity in the test tube, we have thought it worth while to administer it in the treatment of various experimental infections and especially since other investigators have reported results lending some encouragement to these efforts.

Furthermore the studies of Larson and his colleagues and others have indicated the possibility of sodium ricinoleate transforming some of the bacterial toxins into toxoids or other compounds of greatly reduced toxicity in the test tube but retaining their antigenic properties, and thereby of interest from the standpoint of vaccination against diphtheria, scarlet fever, erysipelas, etc. But this is a study in immunity rather than in chemotherapy and has not engaged our particular interest in these investigations, the results of which are briefly summarized in this communication.

#### TOXICITY OF SODIUM RICINOLEATE

The compound employed in this study<sup>2</sup> was prepared by Rider<sup>6</sup> with a high degree of purity and its toxicity determined by intravenous, intraperitoneal, intramuscular and subtheal administration preliminary to trial in the treatment of several experimental bacterial septicemias and toxinemias, trypanosomiasis, syphilis, and poliomyelitis of the lower animals.

(a) *By Intravenous Injection*.—When 2 per cent solutions were given rats intravenously with a gravity apparatus at the rate of 1 c.c. in two minutes, as employed in determining the toxicity of arsphenamine and neoarsphenamine,<sup>7</sup> the maximum tolerated dose permitting animals to survive ten days or longer was approximately 0.035 gm. per kilogram weight (Table I) while 0.050 gm. per kilogram produced death immediately or within one or two days (minimal lethal dose). It is, therefore, about 4 times as toxic as alkalized solutions of arsphenamine by this route of administration. When the injections were given more rapidly and especially with more concentrated solutions, the tolerance was greatly reduced, showing that for this route of administration it is necessary to use more dilute solutions slowly injected.

<sup>2</sup>Kindly furnished by the William S. Merrell Company of Cincinnati, Ohio.

Rabbits have borne 10 daily doses of 0.010 gm. per kilogram and 0.005 gm. per kilogram in as many as 30 consecutive daily doses without untoward effects, except the production of sclerosis and thrombosis of the marginal ear veins and microscopic examination of the lungs, heart, liver, and kidneys have shown practically no histologic evidences of injury. However, the heart and lungs of rabbits and rats succumbing immediately after the injection of lethal doses have shown large emboli of hemolyzed erythrocytes, the whole histologic picture bearing a striking resemblance to those changes described by Kolmer and Lucke<sup>8</sup> following the intravenous injection of acid solutions of arsphenamine, producing intravascular hemolysis and agglutination.

TABLE I  
TOXICITY OF SODIUM RICINOLEATE

| ANIMAL     | ROUTE OF ADMINISTRATION | SOLUTION | MINIMAL LETHAL DOSE PER KILO | MAXIMUM TOLERATED DOSE PER KILO |
|------------|-------------------------|----------|------------------------------|---------------------------------|
| Rat        | Intraven.               | 2.0%     | 0.050 gm.                    | 0.035 gm.*                      |
| Rat        | Intramus.               | 10.0%    | —                            | More than 1.0 gm.               |
| Rat        | Intraperit.             | 4.0%     | 0.5 gm.                      | 0.3 gm.                         |
| Mice       | Intraperit.             | 4.0%     | 0.5 gm.                      | 0.25 gm.                        |
| Guinea pig | Intraperit.             | 4.0%     | —                            | 0.16 gm.                        |
| Guinea pig | Intraspinal             | 0.1%     | —                            | 0.004 gm.                       |

\*Rabbits have tolerated 10 daily doses of 0.010 gm. and 30 daily doses of 0.005 gm. per kilogram without untoward effects.

TABLE II  
HEMOLYTIC ACTIVITY OF SODIUM RICINOLEATE IN WATER-BATH AT 37° C.

| WASHED ERYTHROCYTES |               |            |              | WHOLE DEFIBRINATED BLOOD |        |            |              |

| 1 c.c. 1: 100       | 1 c.c.        | 1: 200     | Few seconds  | 1 c.c. 1: 100            | 1 c.c. | 1: 200     | Few seconds  |
| 1 c.c. 1: 200       | 1 c.c.        | 1: 400     | Few seconds  | 1 c.c. 1: 200            | 1 c.c. | 1: 400     | Few seconds  |
| 1 c.c. 1: 400       | 1 c.c.        | 1: 800     | 15 seconds   | 1 c.c. 1: 400            | 1 c.c. | 1: 800     | About minute |
| 1 c.c. 1: 800       | 1 c.c.        | 1:1,600    | About minute | 1 c.c. 1: 800            | 1 c.c. | 1:1,600    | 20 minutes   |
| 1 c.c. 1:1,600      | 1 c.c.        | 1:3,200    | About minute | 1 c.c. 1:1,600           | 1 c.c. | 1:3,200    | Incomplete   |
| 1 c.c. 1:3,200      | 1 c.c.        | 1:6,400    | 30 minutes   | 1 c.c. 1:3,200           | 1 c.c. | 1:6,400    | Incomplete   |

(b) *Hemolytic and Agglutinating Activity.*—Indeed 1 c.c. of 1:3200 solution of sodium ricinoleate in saline solution is capable of completely hemolyzing 1 c.c. of 5 per cent suspension of washed rabbit corpuscles (final dilution 1:6400) in about thirty minutes at 37° C. (Table II). Even in the presence of plasma, the hemolytic activity of the compound is quite high, since 1 c.c. of 1:800 dilution has produced complete hemolysis of 1 c.c. of defibrinated rabbit blood (final dilution 1:1600) within twenty minutes in a water-bath at 37° C.

Curiously, however, sodium ricinoleate does not produce any marked degree of agglutination of either washed or unwashed erythrocytes in the test tube, and it would appear that intravascular agglutination plays little or no part in toxicity by intravenous injection, although it may be that the emboli found in the heart and vessels of the lungs as well as to some extent in the kidneys are

due to thromboplastic stromas and other debris of hemolysis as suggested by Gerwe<sup>2</sup> and responsible for the respiratory and cardiac failure resulting in death following intravenous injections of lethal amounts.

(c) *By Intramuscular Injection.*—By intramuscular injection, however, the hemolytic and indirect thromboplastic effects of sodium ricinoleate are largely removed and consequently the toxicity is greatly reduced, since rats have withstood doses larger than 1.0 gm. per kilogram of weight (Table I). Not infrequently, however, abscesses have resulted at the sites of injection showing that the compound produces considerable inflammation with liquefaction necrosis by this route of administration, the pus being frequently of a brownish color due to local hemolysis.

(d) *By Intraperitoneal Injection.*—The same has been found true after intraperitoneal injections in rats, mice, and guinea pigs in that upon autopsy extensive inflammatory changes of the parietal and visceral peritoneum was sometimes observed along with light reddish-brown exudates of a soapy nature. Indeed rats and mice usually succumbed within twenty-four hours to doses of 0.5 gm. per kilogram (minimal lethal dose) although single doses as high as 0.25 to 0.3 gm. per kilogram (Table I) were borne indefinitely (maximum tolerated dose). With guinea pigs, however, the maximum tolerated dose was somewhat less being about 0.16 gm. per kilogram which corresponds quite closely to the dose of 0.12 to 0.27 gm. per kilo observed by Gerwe.<sup>2</sup>

(e) *By Intracisternal Injection.*—Since we proposed using sodium ricinoleate in the treatment of tetanus of guinea pigs by intraspinal injection it was necessary to determine its toxicity by this route of administration, and in guinea pigs it was found that the maximum tolerated dose by intracisternal injection was approximately 0.004 gm. per kilo or about one-tenth of the maximum tolerated dose by intravenous injection (Table I).

#### THE EFFECT OF SODIUM RICINOLEATE UPON DIPHTHERIA TOXIN

Along with a large number of other compounds<sup>5</sup> sodium ricinoleate is capable of inactivating diphtheria toxin in the test tube. As shown in Table III as an example of the results of several experiments, an amount as small as 0.0075 gm. dissolved in 1 c.c. of saline solution and added to 6 M. L. D. of diphtheria toxin in 1 c.c. is capable of completely inactivating the latter during an exposure of one hour at room temperature as determined by the subcutaneous injection of the 2 c.c. mixtures into young guinea pigs (8 to 10 ounces). When, however, an L+ dose of toxin is employed, amounts of sodium ricinoleate ranging from 0.003 to 0.030 gm. are unable to completely detoxify this large amount of toxin in the test tube.

Whether or not the detoxified mixtures are capable of engendering immunity, that is, of retaining antigenic activity, has not been definitely determined. In one experiment we partially detoxified 5 L+ doses with 0.1 gm. of sodium ricinoleate dissolved in 50 c.c. of saline and allowed to stand in an incubator for one hour and kept in a refrigerator. Twelve guinea pigs were subsequently given 1 c.c. subcutaneously every five days. Of these 8 died after 5 to 8 injections due to incomplete detoxification of the toxin. Four survived

and three weeks after the last dose were given a subcutaneous injection of 3 M. L. D.'s of toxin sufficient for producing fatal intoxication of 4 controls on the third day after injection; the immunized pigs succumbed in from six to eight days, so that it would appear that but little immunity had been engendered and suggesting that sodium ricinoleate may de-antigenize a portion of diphtheria toxin in vitro.

\* — = survived: D = died.

However, of much more interest from the standpoint of chemotherapy is the question of whether or not sodium ricinoleate is capable of destroying diphtheria toxin in the living guinea pig.

For this purpose animals were given subcutaneous injections of 6 M. L. D.'s of toxin subcutaneously and sodium ricinoleate injected intravenously twenty-four hours later in doses ranging from 0.003 to 0.030 gm. per kilo. In other experiments the sodium ricinoleate was given intramuscularly in doses ranging from 0.1 to 0.5 gm. per kilogram, immediately after the subcutaneous injection of the toxin.

As shown in Table IV the untreated controls succumbed in forty-eight hours after the injection of toxin, as the dose was rather large but purposely selected in order to leave no doubt about the results. But unfortunately the sodium ricinoleate in the doses administered was unsuccessful in every instance in combating the toxemia, although the larger doses sometimes prolonged the lives of the animals by one or two days.

Duplicate tests embracing the intraperitoneal injection of sodium ricinoleate in doses ranging from 0.010 to 0.050 gm. per kilogram four hours after

\*By subcutaneous injection.

†Immediately after injection of toxin.

\*\*Twenty-four hours after injection of toxin.

‡- = survived; D = died.

§Given four hours after subcutaneous injection of toxin and repeated daily for 3 more doses.

the subcutaneous injection of 3 M. L. D.'s of toxin and repeated daily for 3 additional doses gave similar negative results, and as the experiments were repeated several times, it would appear that the compound is incapable of appreciably detoxifying diphtheria toxin in the living animal.

#### THE EFFECT OF SODIUM RICINOLEATE UPON TETANUS TOXIN

Similar results were observed with tetanus toxin except to state that in the test tube, sodium ricinoleate appears capable of detoxifying this toxin to a somewhat greater degree than diphtheria toxin.

For example an L+ dose of tetanus toxin in 1 c.c. of saline solution is apparently completely detoxified by 0.006 gm. of sodium ricinoleate dissolved in 1 c.c. of saline solution in an hour at room temperature as determined by injecting the mixtures subcutaneously into young guinea pigs (Table V).

Even a dose as small as 0.003 gm. detoxified this amount of toxin sufficiently to permit the animals to survive several days after the death of controls injected with the toxin alone.

Unfortunately, however, this inactivated toxin does not appear to possess antigenic value if one may judge from the results of a single experiment in which 5 L+ doses of toxin were added to 0.1 gm. of sodium ricinoleate dissolved in 50 c.c. of saline and incubated for an hour at 37° C. followed by

preservation in a refrigerator. Twelve guinea pigs were given 1 c.c. subcutaneously every five days for 10 doses. One animal succumbed before the series of injections were completed. Three weeks after the last dose the remaining

\* - = survived: D = died.

11 were given a subcutaneous injection of one-one-hundred-fiftieth of an L+ dose of toxin sufficient to cause the death of 4 controls on the third day. All of the immunized animals died in from five to eleven days, indicating that some immunity had been produced, but likewise, suggesting that sodium ricinoleate tends to de-antigenize a portion of this toxin as was probably also true of diphtheria toxin previously described.

But it would appear that sodium ricinoleate is capable of detoxifying tetanus toxin to some slight extent in the living animal.

Controls injected subcutaneously with one L+ dose of toxin died of tetanus intoxication in about forty-eight hours, whereas when 0.5 gm. of sodium ricinoleate was given intramuscularly, immediately after the toxin, some animals lived for one or two days longer (Table VI).

Controls injected subcutaneously with one-one-hundredth of the L+ dose died of tetanus in about three or four days, whereas the intramuscular injection of sodium ricinoleate in doses of 0.1 to 0.5 gm. per kilo immediately after the injection of toxin, prolonged the lives of some animals by one or two days.

Intravenous injections of 0.003 to 0.030 gm. per kilo twenty-four hours after the injection of toxin had no appreciable effect and the same was generally true of intraperitoneal injections. In the latter experiments guinea pigs were given subcutaneous injections of one-one-hundredth of the L+ dose of toxin sufficient to produce fatal tetanus intoxication in from three to four days. Four hours after the injection of toxin sodium ricinoleate was given intraperitoneally in doses varying from 0.010 to 0.040 gm. per kilo and repeated daily for 4 addi-

tional doses. All of the animals, however, developed tetanus and died in from four to six days, living, therefore, but a few days beyond the controls (Table VI).

Additional guinea pigs were given subcutaneous injections of one-one-hundredth of the L- dose of toxin and four days later when symptoms of tetanus first appeared were given 0.003 gm. of sodium ricinoleate intraspinally. This dose was repeated daily for 2 additional doses but all of the animals died in five or six days while the untreated controls succumbed in three or four days (Table VI).

\*By subcutaneous injection. \*\*Immediately after injection of toxin.

†Twenty-four hours after injection of toxin. ‡- = survived; D = died.

These experiments repeated several times have shown, therefore, that sodium ricinoleate may have a slight degree of detoxifying activity for tetanus toxin in vivo; the doses of toxin were relatively large in order to produce death from tetanus of all of the controls which may have masked more evidence of detoxification in these experiments.

#### THE BACTERICIDAL ACTIVITY OF SODIUM RICINOLEATE

Sodium ricinoleate has a low bactericidal activity in the test tube.

When tested according to the Reddish method against *Staphylococcus pyogenes aureus*, it was found that whereas a 20 per cent solution was completely

bactericidal for this organism in an exposure of five minutes, yet 10 and 5 per cent solutions were not completely bactericidal in exposures as long as one hour. These results correspond closely to those of Gerwe<sup>9</sup> who also found the phenol coefficient for *B. typhosus* very low.

By the bacteriostatic method of Kolmer,<sup>10</sup> however, we have found that 1:4,000 concentrations of sodium ricinoleate inhibited the growth of *Staphylococcus aureus* in broth medium while 1:600 dilutions were bactericidal. With *Streptococcus hemolyticus* dilutions of 1:60,000 were bacteriostatic and 1:40,000 bactericidal; with *Pneumococcus* (Type I) dilutions up to 1:80,000 were bacteriostatic and 1:60,000 bactericidal.

#### SODIUM RICINOLEATE IN THE TREATMENT OF VARIOUS EXPERIMENTAL INFECTIONS

*In Streptococcus Cellulitis and Peritonitis of Mice.*—White mice were given intraperitoneal injections of 0.6 c.c. of twenty-four-hour broth cultures of *Streptococcus hemolyticus* and four hours later intraperitoneal injections of sodium ricinoleate in doses varying from 0.050 to 0.250 gm. per kilogram of weight.

The culture was of such virulence that the 8 untreated controls died of the resulting peritonitis and septicemia in about forty-eight hours, all animals showing positive heart blood cultures at necropsy.

All of 20 mice receiving the compound died, however, in the same period of time so that single doses of sodium ricinoleate of the amounts employed were without appreciable effect. All of these mice, likewise, showed positive heart blood cultures.

Fourteen additional mice were infected with the same dose of culture by injection under the skin of the thorax. Four untreated controls died in from three to five days of the resulting cellulitis and with positive heart blood cultures obtained at autopsy.

Ten mice were given intraperitoneal injections of single doses of sodium ricinoleate, likewise varying from 0.050 to 0.250 gm. per kilogram of weight, but all of these also perished in about the same period of time as the untreated controls from the local abscesses associated with the septicemia (positive heart blood cultures).

From these experiments it appeared that sodium ricinoleate by intraperitoneal injection was without appreciable curative effects in streptococcus cellulitis and peritonitis of mice. It is true, however, that the infections were very severe but unfortunately this is a difficulty in the chemotherapy of experimental streptococcus infections of mice in that smaller doses of the organism permits some untreated controls to live indefinitely and therefore making it difficult to evaluate the results of treatment. On the other hand the rapidly fatal experimental infections have no parallel in streptococcus infections of the human being and may readily enough mask some degree of curative activity on the part of the compound under study.

*In Pneumococcus Peritonitis and Septicemia of Mice.*—Similar negative results were observed in the treatment of mice infected with a highly virulent culture of Type I pneumococcus.

Eight mice injected intraperitoneally with 0.3 c.c. of a 1:40,000 dilution of twenty-four-hour broth culture died in about forty-eight hours with positive heart blood cultures (septicemia). Twenty additional mice infected at the same time were given single doses of sodium ricinoleate intraperitoneally four hours later in doses varying from 0.006 to 0.050 gm. per kilogram of weight. All of these, likewise, succumbed in about the same time as the untreated controls, so that in this single experiment there was no evidence of curative activity on the part of the compound administered by intraperitoneal injection.

*In Tuberculosis of Guinea Pigs.*—A series of 24 guinea pigs weighing from 280 to 400 gm. were given subcutaneous injections in the neighborhood of the inguinal glands of 0.005 gm. of human tubercle bacilli. Four untreated controls died of the resulting infection in from twelve to eighteen days.

One week after infection 20 of the animals were given intraperitoneal injections of sodium ricinoleate in doses varying from 0.030 to 0.100 gm. per kilo of weight and the injections repeated every three days. Two of the animals receiving the 0.100 gm. dose died after three injections from the toxicity of the drug and before tuberculous lesions had well developed. From 2 to 8 injections of sodium ricinoleate were given the 18 remaining animals, but all died of widespread tuberculous infection in from eight to twenty days, so that the compound was without appreciable curative effects. Indeed a number of the animals receiving the larger doses of sodium ricinoleate died a few days earlier than the untreated controls and suggesting that their resistance to tuberculous infection had been reduced by the compound.

*In Syphilis of Rabbits.*—Eight rabbits were given intratesticular inoculations with our Nichols-Hough strain of *Spirocheta pallida*. One month later two untreated controls developed acute bilateral orchitis with numerous spirochetes in dark-field examinations.

One week after testicular inoculation 6 of the rabbits were given 0.003 gm. of sodium ricinoleate per kilogram of weight by intravenous injection, and the dose was repeated daily for a total of 8 injections.

All of these animals likewise developed acute testicular syphilis with positive dark-field examinations in about a month, so that the compound was without any demonstrable curative effects in this single experiment.

*In Trypanosomiasis of Rats.*—White rats weighing from 110 to 300 gm. were given intraperitoneal injections of approximately 500,000 *Tryp. equiperdum*. Four untreated controls died of the resulting infection in from three to four days and showed enormous numbers of the trypanosomes in the tail blood.

Twenty-four hours after infection and before parasites appeared in the peripheral blood, 20 of the rats were given single intravenous injections of sodium ricinoleate in doses varying from 0.005 to 0.025 gm. per kilogram of weight. All of these likewise succumbed to trypanosomiasis in from three to four days and showed enormous numbers of parasites in the peripheral blood, so that the compound was without appreciable trypanocidal activity in this single experiment.

*In Acute Poliomyelitis of Monkeys.*—Three monkeys were inoculated intracerebrally with an emulsion of monkey poliomyelitic spinal cord kindly fur-

nished by the Rockefeller Institute. The first clinical evidences of poliomyelitis was apparent in from seven to nine days, and an untreated control died of paralysis twenty-one days after inoculation.

The two remaining animals were given sodium ricinoleate in dose of 0.005 gm. per kilogram on the seventh day after inoculation when signs of infection were first apparent and the dose repeated daily for a total of five injections. Both animals died in from eighteen to twenty-two days from progressive paralysis, so that sodium ricinoleate was without demonstrable curative effects in these two animals, a more complete description of the experiment being given in a separate communication.<sup>11</sup>

#### SUMMARY

1. Sodium ricinoleate (sorcin) is compound of particular interest from the chemotherapeutic standpoint because of the possibility of inactivating toxins and other bacterial agents in the blood.

2. Its toxicity has been determined by intravenous, intraperitoneal, intramuscular and subtheal injection in the lower animals.

3. It is highly hemolytic and upon intravenous injection may produce intravascular hemolysis with embolism. The maximum tolerated dose by this route of administration has been found to be approximately 0.035 gm. per kilo.

4. By intramuscular injection it may produce local irritation with liquefaction necrosis when large amounts are injected. However it is well borne systematically by this route of administration as the maximum tolerated dose has been found to be more than 1 gm. per kilo.

5. It may also produce some irritation upon intraperitoneal injection but is well borne by this route, since the maximum tolerated dose is as high as 0.16 to 0.3 gm. per kilo.

6. By intracisternal injection the maximum tolerated dose has been found to be approximately 0.004 gm. per kilo.

7. Sodium ricinoleate is capable of inactivating or destroying diphtheria and tetanus toxins in the test tube and is especially destructive for the latter, although it would appear that the resulting toxoids are of low antigenic activity.

8. Sodium ricinoleate is but feebly antitoxic for the toxins of diphtheria and tetanus bacilli in guinea pigs by various routes of administration.

9. Sodium ricinoleate is of very low bactericidal activity in the test tube and has been found without demonstrable curative activity in severe streptococcal, pneumococcal, and tuberculous infections of the lower animals as well as in experimental trypanosomiasis of rats, syphilis of rabbits, and acute anterior poliomyelitis of monkeys.

## THE SPECIFIC GRAVITY OF THE BLOOD IN HUMAN CANCER\*

### FOUR HUNDRED OBSERVATIONS, WITH A NOTE ON ITS CLINICAL SIGNIFICANCE

DAVID POLOWE, M.D., PATERSON, N. J.

**NORMAL Values.**—The normal specific gravity of the whole blood has been fairly consistently found to be about 1.055 for males and 1.053 for females (Jones,<sup>1</sup> Schmaltz,<sup>2</sup> Lyonnet,<sup>3</sup> Leake, Kohl, and Stebbins,<sup>4</sup> Polowe<sup>5</sup>). A diurnal variation was noted by Jones, Leake et al., and Polowe, the specific gravity of the whole blood being about 0.002 higher in the morning than in the afternoon. For the purposes of this study specific gravity values below 1.050 were considered as representing a state of anemia, while values above 1.060 were considered as representing a higher than normal density of the whole blood.

**Literature.**—No large series of observations on the specific gravity of the whole blood in human cancer has been made in recent years. Lloyd Jones, in 1887, reported a series of 15 cases. His lowest blood density was 1.031 obtained in a case of carcinoma of the uterus. But even in this small series he called attention to the fact that normal specific gravity values may be found in advanced cases of cancer. Schmaltz, in 1891, reported one case of carcinoma of the stomach in which a specific gravity of the blood of 1.039 was found. Polowe,<sup>6</sup> in 1929, reported his findings in 23 cases of proved carcinoma. He stated at that time that, "the more severe anemias occurred in carcinoma of hidden or not readily accessible areas (gastrointestinal tract, peritoneum, pancreas, urinary bladder). Carcinoma of other parts of the body did not seem to alter the normal blood density, even though most of the cases were quite advanced."

\*Received for publication, September 20, 1933.

This work has been aided by a grant from the Committee on Scientific Research of the American Medical Association.

*The Clinical Significance of the Specific Gravity of the Blood in Human Cancer.*—(a) Any discussion of the specific gravity of the blood presupposes the idea that a change in the quality of the blood is at once manifested by a change in its specific gravity. Such a change may be brought about by an alteration in the number of erythrocytes, leucocytes, platelets; by alteration of the hemoglobin content, fibrinogen content, ash content; by alteration of the lipid values; and by shifting water balances. In anemia associated with cancer\* (as in the anemia associated with other clinical entities) no one factor alone may be incriminated as the sole agent which so materially affects the weight of the blood.

Lucas,<sup>7</sup> in a very recent publication on the diagnosis and treatment of the anemias of cancer, states that if one searches diligently enough the cause of such anemias can usually be found and treated. He states further: "Anemia obviously may result from an increased destruction or loss of blood, from a decreased blood formation, or combination of these two. Decreased blood formation frequently is preceded by a chronic blood loss or destruction. Chronic and acute hemorrhage is usually not difficult to find so that we are chiefly concerned with decreased blood formation due to nutritional deficiency or to the inability of the patient to assimilate food properly." Lucas mentions the following known values to aid in determining the hematopoietic needs of the patient:

1. Red blood cell count
2. The percentage hemoglobin
3. The mean corpuscular volume
4. The color index
5. The free HCl of the gastric contents
6. The saturation index

I have quoted Lucas rather fully because I feel that for the average practitioner the specific gravity of the whole blood offers a rapid orientation of the status of the blood at any given moment and includes at least three (1, 2, and 3 above) of the needed values, and possibly five (the saturation index and, in cases of secondary anemia, the color index). Interpolations of specific gravity values into the above values may be made roughly by experience with the method or quite accurately by the use of Guthrie's comparison chart.<sup>8</sup> One should not forget the use of one's clinical judgment in evaluating any of these findings, including the specific gravity of the blood.

Factors that tend to increase the blood density should also be kept in mind when evaluating the blood status in any given case. An absolute increase in blood density may be brought about by an increase in the production of any of its various constituents. Examples of this may be found in polycythemia vera wherein the erythrocytes are markedly increased in number, though one should note that in this condition the percentage hemoglobin is relatively low; in hyperparathyroidism the increased calcium content of the blood increases the blood density. A relative increase in blood density may be brought about by dehydration due either to lack of fluid intake, lack of fluid intake plus anuria (Popel's<sup>9</sup> work on dogs), or to loss of fluids by excessive diaphoresis, emesis,

\*The term "anemia of cancer" should perhaps be avoided. The term "anemia associated with cancer" is suggested to emphasize the clinical fact that the anemia associated with cancer is almost never due to the cancer process itself.

diarrhea, or combinations of these. A relative increase in blood density may also be brought about by venostasis (Copeman's<sup>10</sup> work on rabbits) due to cardio-respiratory diseases or due to actual mechanical obstruction of the venous return by masses in the axilla, neck, thorax, and abdomen as may sometimes be seen in advanced cases of neoplastic disease. In the clinical evaluation of the blood status of the dehydrated carcinomatous patient I have found that the relatively high hemoglobin percentages found are often belied by low specific gravity values of the whole blood, the latter values being more in keeping with the clinical appearance of the patient. Examples of this may be found in cases of obstructive lesions of the stomach wherein vomiting (with due respect paid to starvation effects) causes not only a loss of water but of minerals, such as chlorides, as well. This produces a mineral imbalance between the blood stream and the tissue fluids which is more truly, though not ideally, reflected by the specific gravity of the whole blood than by the estimation of the now concentrated erythrocyte and hemoglobin values. An emotional anhydremia in needle-shy patients has been reported by Barbour and Hamilton.<sup>11</sup>

(b) The following is a study of the blood status associated with human cancer in terms of the specific gravity of the whole blood. The falling drop technic of Barbour and Hamilton<sup>12</sup> was used. The blood was obtained from the capillary bed at the finger tip. In lesions of the breast, axillae, and upper extremities, where only one side was involved, the finger on the sound side was selected to obviate as much as possible the venostatic effect of mechanical pressure.

Single observations were made on 400 cases of proved cancer (Table I) and, as a control on 50 cases of proved benign neoplasms and noncancerous lesions (Table II). Table III represents a further control group of 50 cases, in summary form, of average run, nonneoplastic conditions as found in a general hospital, the details of which were published elsewhere.<sup>3, 6</sup> Tables IV, V,

of the radiosensitivity of the cancerous growths in the last 300 cases observed. Table VIII represents the cases of anemia found in the noneancerous group of lesions.

In the series of 23 cases I reported in 1929, ten, or 43 per cent, fell into the anemic group. This is in striking contrast to the present larger series of 400 observations where the corrected incidence of anemia was found to be 22 per cent. This may be explained not alone by the greater accuracy obtained in observing a larger series, but also by the fact that the smaller series was observed in hospitalized patients, usually late stages of cancer, whereas the larger series was compiled almost wholly (with the exception of about 6 cases) from ambulatory, out-patient cases. This low incidence of the anemias associated with early, ambulatory cases of cancer emphasizes the belief that cancer, at least in its beginnings, is a local disease. The 22 per cent incidence compares favorably with the 30 per cent incidence of anemias associated with neoplasms other than those of cancer; it contrasts strikingly with the 42 per cent of combined hospital and clinic patients (85 cases) of a general hospital as reported by Polowe,<sup>6</sup> and still more strikingly with the 52 per cent of purely hospital cases as noted in Table III.

This low incidence of anemia of 22 per cent bears further comment. It tends to minimize the current idea that irradiation of the cancerous growths produces anemia. I do not have the exact data as to how many of the observed cases were under radiation treatment, but I do recall that most of them had received some such treatment.\* Lucas<sup>7</sup> feels that this factor as a cause of anemia is overemphasized. Examination of Tables IV, V, and VI tends to bear this out. Only 1.4 per cent of the observations (Table I) fell into the group of severe anemias. All four were in cancer of the stomach. Only 3.8 per cent of the observations fell into the moderately severe group of anemias. The majority of these were associated with cancer of the cervix and of the rectum. The balance of 16.8 per cent fell into the mild group of anemias. The lesions encountered were mainly those of the gastrointestinal tract, and those of the genitourinary tract (urinary bladder, testis, cervix). All of these three groups of anemias can be plausibly explained on a clinical basis (the presence of large ulcerated areas from which there is a constant oozing of blood and through which bacteria gain easy access to the body). Starvation and dehydration are no mean factors in the cause of anemia associated with cancer of the gastrointestinal tract. Irradiation should not, therefore, be considered an important factor in the production of anemia.

Starvation, hemorrhage, and infection form the great etiologic triad in the production of the anemias associated with cancer. The nature of this study (i.e., the single observations and the lack of follow-up) prevents an accurate interpretation of the blood status case by case. However, the number observed, plus some clinical note on each case, plus clinicopathologic follow-ups on some of the cases enable me to give a fair cross-section of my clinical impressions as

\*My notes show that in the breast series 18 cases (18 per cent) were treated by some form of irradiation. Of these only one fell into the anemic group (mild, with specific gravity of 1.048). Sixteen had blood densities within normal limits. One had a blood density of higher than normal, 1.061, and had received treatment with radium tubes and high voltage cycle.

to the factors determining the variation of the percentage of anemias in the various clinics. Thus two main groups stand out: (a) Cancer of the easily visible portions of the body as found in the breast, skin, oral, and gynecologic clinics. It is plausible to assume that the percentage of anemias is less in this group since the lesions are discovered earlier by the patient and are, therefore, treated earlier. (b) Cancer of the hidden portions of the body as found in the gastrointestinal and urologic clinic. It is plausible to assume that the percentage of anemias is greater in this group as the patient usually discovers his condition when the growth has advanced and usually long after starvation, hemorrhage, and infection have made inroads into his body economy.\*

In the sarcomas attention is invited only to the fact that those involving bone (a blood-forming organ) exhibit at least half again a greater incidence of anemia than do those involving the nerves.

The group of higher than normal blood densities shown in the last two columns of Table I deserves comment. I cannot explain the high blood density in all the cases, but my clinical notes indicate that venestasis may be an important etiologic factor. Thus of the 13 breast cases one patient was noted as being inoperable, one was noted as having edema, and 7 were postoperative cases with possible interference of venous return, though my notes do not specifically show that in these 7 cases. In the group of 5 patients with epitheliomas, one patient with a specific gravity of 1.062 is noted as having a squamous carcinoma with metastasis to the axillary nodes, one patient with a specific gravity of 1.064 is noted as having a squamous carcinoma with clubbed finger tips, the other three patients are noted as having squamous carcinomas on hands and arms. In the neurogenic sarcoma group, of the 4, one involved the left forearm and the other a right lower extremity, but my notes do not indicate that there was involvement of the regional lymph nodes, which if present might account for an increased blood density. One melanosarcoma is noted as involving the right axilla. One extensive angiosarcoma of the back was associated with a specific gravity of the blood of 1.062.

In this group of higher than normal blood densities, it is the negative phase which compels attention. Thus, no high blood densities appear in any of the gastric cases. It is in this clinic that I saw cases of dehydration where one would expect a high blood density (especially in view of the normal or nearly normal red blood cell counts and hemoglobin values that were found). But such was not the case. Other factors, such as loss, by emesis, of ash content of the blood, and factors as yet undetermined tend to produce a blood density more in keeping with the clinical picture. The same is true of cancer of the large bowel where only one case (1 per cent) was found to have a blood density of 1.061.

It must be borne in mind that the complexities of the forces at play, such as the fluctuating water and mineral balances and the destroyed rhythm of blood formation, tend at times to produce normal specific gravity values while pathologic forces are destroying the patient. The importance of clinical judgment is obvious.

\*A striking example of this was seen in Case G-12, Table IV, carcinoma of the stomach in a male, aged fifty-two, wherein a blood density of 1.031 (the lowest density observed in the entire series) was found six days prior to perforation of the stomach.

Just a note in passing on the benign group of higher than normal blood densities. One case only deserves comment, that of a boy of nineteen, with a bone cyst, wherein the specific gravity of the blood was 1.061. This high blood density may have been due to an increased calcium content of the blood. The high specific gravity of the blood may be of differential diagnostic value in such cases.

(c) *Grading and Sensitivity.*—In Table VII one sees that 20 per cent of the cases graded fell into the anemic group, the more malignant grades (II and

III) claiming the greatest number. This 20 per cent is in keeping with the 22 per cent incidence of the anemias in the 400 cases observed. Of the radio-resistant lesions 21 per cent fell into the anemic group. Here again the incidence is in keeping with the 22 per cent for the entire series. Of the radiosensitive lesions 10 per cent fell into the anemic group. No radiosensitive lesions were found in the severe and moderately severe groups of anemias (Tables IV and V). It appears quite likely that the low incidence of radiosensitive lesions among the anemias is due to their rapid growth and consequent early discovery by the patient who presents himself for treatment before anemia has set in.

From a statistical point of view, therefore, radioresistance is only coincidentally associated with an anemic status.

In 23 of the 31 lesions estimated as being radiosensitive, qualifying terms such as "relatively radiosensitive" or "moderately radiosensitive" were used. The estimate of sensitivity made by the pathologist appears to be ultimately conditioned by the size, location, and accessibility of the growth. Borak<sup>13,14</sup> terms these the conditional and constitutional factors, the conditional factors being determined by the character of the surrounding tissues, including regional and distant organs; the constitutional factors being determined by the nature of the tumor and of its matrix. It should be noted that Borak qualifies his conclusions by stating that, in addition to these biologic factors, the rôle of other clinical factors and the physical properties of the rays must be considered for prognosis and technic of irradiation. Pack and Quimby<sup>15</sup> state that radioresistance is a latent property of cancer tissue. They cite Canti as properly suggesting that "in the case of neoplasms there may be an indirect factor playing an important part." The nature of this indirect factor is not mentioned. Nemenow<sup>16</sup> feels that since the roentgen rays influence the metastructure of the cells, the molecules and atoms, it is as a rule impossible to estimate the radio-sensitivity on the basis of the histologic picture that reveals only the gross structure of the cell. To me, this seems like a hint that cellular chemistry may be a factor of influence.

Several men have thought it likely that the blood status influenced the sensitivity of the tumor process. Dean,<sup>17</sup> ten years ago, made the statement, "The relationship between our skin tests, the therapeutic results and the patients' blood quality has been so close as to warrant the prediction of the effect of therapy within certain limits on the basis of the latter factor alone." Dean found that the usual skin erythema dose had no effect on the anemic patient. After blood transfusion in such a case, Dean obtained a skin erythema with the usual dose. More recently, Stewart<sup>18</sup> very clearly presented the status of estimated sensitivity and observed results of irradiation of pathologic tissues. He stated, "The entire situation suggests the presence of some entirely unknown factor or factors influencing the sensitivity of the tumor process." Stewart further stated that, "After all, the only law of radiosensitivity which remains essentially unchallenged is that one accomplishes very little by irradiating a cachectic patient, unless the cachexia results from a highly sensitive tumor of the type of lymphosarcoma, thymoma, Wilms's tumor and the like." My own impression (stated here merely as a matter of record and as a subject for future investigation) is that there is some underlying electrolytic factor in the blood, whether the patient is anemic or not anemic (I have in mind a chloride retention), which in some way hinders the selective action of the rays. This impression is based on the work of Stammer and Moraczewski,<sup>19</sup> Macht and Teagraden,<sup>20</sup> and on some of my own unpublished work. This remains to be proved. I feel that the anemia is only coincidental, and that when it is associated with a radioresistant lesion, it (the anemia) is then only a clinical expression of a modified electrolytic content of the blood and should be so treated (as by transfusion) before irradiation of the patient.

## SUMMARY

1. The specific gravity of the whole blood was determined in 400 cases of proved cancer. A relatively low incidence of anemia was found: 22 per cent of the series as a whole; 5.2 per cent incidence of combined severe and moderately severe grades of anemia.

2. These anemias can usually be explained on a clinical basis as secondary effects of the cancer process and may so be treated.

3. Anemia appears to be only coincidentally associated with radioresistant lesions.

4. It appears that irradiation as a cause for anemia is overestimated.

5. Venestasis may be an important etiologic factor in the production of higher than normal blood densities.

6. The falling drop technic for determining the specific gravity of fluids offers an easy, rapid, and accurate orientation as to the status of the blood at any moment. It permits of limited differential diagnostic value in gastric lesions wherein low blood densities (expressive of severe or moderately severe grades of anemia) may make one lean toward a diagnosis of cancer.<sup>6</sup> In bone lesions, where hyperparathyroidism is suspected, higher than normal blood densities may add corroborative evidence.

The author wishes to express his appreciation to the various members of the staff of the Memorial Hospital, New York, for their kind assistance in obtaining the correct material and for the time given me in informal discussion of the work. The author alone is responsible for the opinions expressed in this paper. I wish also to thank Sarah Dimond Abrash, A.B., Paterson, N. J., for her aid in the recording of the data.

# LABORATORY METHODS

---

## DETERMINATION OF THE STROKE VOLUME OF THE HEART\*

---

ALEXANDER G. KELLER, JR., PH.G., B.Sc., PHILADELPHIA, PA.

---

THERE is an occasional demand in routine laboratories to determine the stroke volume of the heart in connection with cardiac constriction cases. This may be obtained by determining the oxygen content of venous and arterial blood and the oxygen consumption of the lungs.

*Principle.*—The one-minute oxygen consumption of an individual at rest and fasting for several hours is determined using a basal metabolism apparatus. The pulse is recorded; the oxygen content of venous and arterial blood is determined. The stroke volume can then be calculated.

*Method.*—A. The oxygen consumption of the patient is determined by means of a basal metabolism apparatus. The temperature of the oxygen in the apparatus is noted, also the barometric pressure. The number of cubic centimeters of oxygen consumed per minute is converted to standard conditions by calculation.

B. About 5 c.c. of blood are withdrawn from a vein in the arm of the patient. The blood is protected from contact with air by using a Kaufman Luer double tip syringe, the side arm is connected by rubber tubing containing mineral oil to a test tube lined with approximately 25 mg. of sodium oxalate. A like amount of blood is withdrawn in a similar manner from an artery located in the wrist of the patient.

The pulse of the patient is recorded.

Sodium hydroxide solution: A 2 per cent solution of sodium hydroxide is aerated by introducing it into a separatory funnel and shaking it several minutes.

Oxygen reagent: Potassium ferrieyanide 3 gm., saponin 3 gm., caprylic alcohol 3 c.c., and distilled water, a sufficient quantity to make 1,000 c.c.

Using a van Slyke and Cullen CO<sub>2</sub> Pipette, 7.5 c.c. of the oxygen reagent are introduced into the cup of the apparatus and deaerated by subjecting it to repeated negative pressures. When the reagent is gas-free, 6 c.c. are forced up into the cup of the apparatus. Two cubic centimeters of venous blood are transferred from under the oil in the test tube to the cup of the CO<sub>2</sub> pipette, slowly being delivered under the reagent simultaneously being permitted to enter the chamber of the pipette followed by 5 c.c. of reagent. The excess of reagent is removed from the cup of the pipette. A few drops of mercury are introduced to act as a stopcock seal.

---

\*From the Laboratories of the Graduate Hospital, University of Pennsylvania.  
Received for publication, August 5, 1933.

Most of the mercury is evacuated from the chamber of the pipette and the apparatus is shaken until the gases liberated from the blood by the reagent give a constant volume. (Shake from five to ten minutes.) The gases are oxygen, nitrogen, and carbon dioxide. A negative pressure is now produced in the chamber of the pipette by bringing the upper surface of the liquids to the 2 c.c. graduation. The cup of the pipette is rinsed with distilled water, and 0.5 c.c. of aerated sodium hydroxide is permitted to enter the chamber of the pipette followed by a few drops of mercury. One minute is allowed for the sodium hydroxide to combine with the carbon dioxide gas. The gases (oxygen and nitrogen) are now brought to atmospheric pressure and a reading taken. The temperature and barometric pressure are noted during the analysis.

C. The oxygen content of arterial blood is determined in the same way as that of venous blood.

#### Calculation.—

- A. A—c.c. of  $O_2$  consumed per minute (from basal metabolism apparatus)

$P_1$ —mm. barometric pressure

$P_2$ —760 mm.

$T_1$ —Absolute temperature of gas

$T_2$ —273 degrees Absolute

A.V.T. = Aqueous vapor tension

$$O_2 \text{ c.c. consumed per minute} = \frac{A \times T_2 \times (P_1 - A.V.T.)}{T_1 \times P_2}$$

- B.  $O_2$  in *venous blood*.

B = c.c. of  $O_2 + N_2$  in blood.

$$\text{Volume per cent } O_2 = \left[ \frac{P_1 - A.V.T.}{760 (1 + 0.00367 \times ^\circ C)} \times 50 \times B \right] - 1.36$$

1.36 = Volume per cent of  $N_2$

- C.  $O_2$  in *arterial blood*.

Use the same formula as for oxygen in venous blood.

- D. Minute volume of blood in cubic centimeters =  $\frac{100 \times \text{c.c. } O_2 \text{ consumed per minute}}{\% O_2 \text{ in "C" } - \% O_2 \text{ in "B"}}$

$$\text{Stroke volume in cubic centimeters} = \frac{\text{Minute volume of blood in c.c.}}{\text{Pulse}}$$

Normal stroke volume for patient at rest is from 50 to 100 c.c. in each ventricle per beat.

## THE PREPARATION AND USE OF COLLOIDAL CARBON SOLUTIONS\*

J. M. LOONEY, A.B., M.D., AND F. C. STRATTON, B.S., WORCESTER, MASS.

DURING an investigation undertaken a number of years ago, by the senior author, of the chemical changes in the spinal fluid responsible for the flocculation of the gold sol in the colloidal gold test, it was found that no correlation could be drawn between the two factors because of the variability of the gold sol.

It was found that two gold sols, even though prepared at the same time with the same reagents under the same conditions, did not give identical curves with the same spinal fluids. It was further found that one could not keep a satisfactory gold sol for a sufficiently long time to carry out a series of experiments which would extend over a period of months. In order to carry out the investigation as planned, it was necessary either to have a colloidal solution which could be made in large amounts that would keep indefinitely, or else to have one which could be made at different times and still yield identical results with spinal fluids.

As none of the colloidal solutions then being used could satisfactorily meet these requirements, a search was made for other colloids. After a number of solutions were investigated, it seemed that a colloidal suspension of carbon offered most promise of fulfilling the requirements. A preliminary report on the preparation and use of colloidal carbon solutions was presented at the meeting of the Federation of American Societies for Experimental Biology in 1927.<sup>1</sup> In 1928, at the Philadelphia meeting of the Interurban Clinical Club, a paper was presented giving results of further studies with the method. At this time it was pointed out that solutions of India ink would give similar results, although the reagent was not as sensitive as the electrolytic ones.

A further demonstration of this method was made at the International Physiological Congress at Boston in 1929. At that time a carbon solution made three years previously was used with spinal fluids obtained through the courtesy of Dr. Frank Fremont Smith of the Department of Neurology at Harvard Medical School. The carbon curves in every instance agreed with those obtained independently in his laboratory by the colloidal gold test. The curve of patient M. B. in Table VI was obtained with this solution. Recently Schube and Harms<sup>2</sup> have published an article confirming in part these findings, although no reference was given as to the original investigations of Looney.

Received for publication, August 1, 1933.

## METHOD

The preparation of colloidal solutions of carbon is readily accomplished by means of electrolysis between two carbon electrodes in a faintly acid medium. Solutions prepared by acid alone are as a rule not stable, but the addition of an oxidizing agent such as potassium dichromate increases their stability.

The carbon electrodes are obtained from discarded dry cells and it is preferable to use electrodes which have not been impregnated with paraffin. These are connected in series with a 22 ohm rheostat, capable of handling 5 amperes, an ammeter and the terminals of a 110 volt source of direct current. A volt meter is connected across the two electrodes which are immersed in a jar containing three liters of water to which has been added 3 ml. of concentrated sulphuric acid saturated with potassium dichromate. The desired amperage and voltage were obtained by regulating the distance between the electrodes and by manipulating the rheostat. Current was passed through the solution for from ten to twenty hours, yielding a black solution of carbon in colloidal suspension. After standing for several days the clear supernatant solution was decanted from the larger particles which had settled out. A good solution should be clear, dark brownish in color, and of such concentration that print can be distinguished through a layer 5 or 6 mm. in thickness. This depth of color can be obtained by diluting with distilled water. Pale solutions should be discarded.

When added to spinal fluids, varying degrees of precipitation may be observed and utilized as with colloidal gold solutions to yield a curve. The following scale has been used in recording observations:

- 0—no change
- 1—no precipitate, change in color
- 2—light precipitate, deep color
- 3—heavy precipitate, marked color
- 4—heavy precipitate, faint color
- 5—completely colorless

Eleven tubes were set up as for colloidal gold curves, 1 ml. of 1.0 per cent sodium chloride solution placed in each tube, and 1 ml. of spinal fluid added to the first tube. After thorough mixing 1 ml. was transferred from the first tube to the second, mixed thoroughly, and the process repeated to give a series of dilutions  $\frac{1}{2}$ ,  $\frac{1}{4}$ ,  $\frac{1}{8}$ , etc., the 1 ml. for transfer from the tenth tube being discarded, and the eleventh tube acting as control. Two ml. of the colloidal carbon solution were added to each tube, the racks shaken and allowed to stand overnight.

In Table I are given some of the preliminary experiments carried out during 1927 and 1928. It will be noted in Case 1 on March 15 that different carbon solutions give somewhat different results although the curves are of the same type. The character of the curve changed as the patient recovered so that it approached that of the normal in which precipitation occurs only in the first two tubes. That the curve obtained in meningitis differs in character from that obtained in general paresis is also evident from this table.

Although these cases showed that colloidal carbon solutions appeared to be suitable as a test medium, it was felt that a thorough study of all the factors influencing the sensitivity of the solutions was needed before the method could be used clinically.

The sensitivity of the reagent is influenced by the conditions of preparation and also by the salt concentration and  $P_H$  of the solution used to make the spinal fluid dilutions. Solutions were prepared using a current density of 2, 3, and 4 amperes at potentials of 20, 30, and 40 volts.

It was found that solutions prepared at the higher voltages were as a rule too unstable for use. Thus, of 7 samples made at 40 volts, 6 precipitated out completely after a few days' standing, and the seventh was so sensitive that the addition of 1 per cent salt solution caused complete precipitation. The samples prepared at very low voltages and amperages did not as a rule contain sufficient carbon to make them available for study. Stable solutions

could be prepared at from 20 to 30 volts and from 3 to 4 amperes. The solutions made at 4 amperes were considerably more sensitive than those made at 3 amperes. The samples prepared with electrodes having a small surface area immersed in the solution were on the whole more sensitive than those having the same voltage and amperage but with a greater area of electrode in the bath. The best preparations are obtained with fresh electrodes immersed to a depth of from 13 to 14 cm. at 30 volts and 3 amperes. These solutions contain the maximum amount of carbon, about 250 to 270 mg. being contained in each 100 ml.

Variation in the sensitivity and stability of the solutions can be obtained by altering the salt concentration of the solution used in making the spinal fluid dilutions. This influence of the salt solution upon the sensitivity of the reaction is shown in Table II, which records the data when the dilutions were

made with distilled water, 1.0 per cent, and 1.5 per cent sodium chloride solutions. Increase in the salt concentration increases the sensitivity.

The stability of the carbon solutions on standing is a function of the sensitivity of the colloid. The less sensitive solutions can be kept for long periods, as is shown by the fact that the solution used for demonstration at the International Physiological Congress in 1929 had been prepared three years previously. On the other hand, extremely sensitive solutions have a tendency to precipitate out so that they are too light to use. Thus we find that Sample 6, when three weeks old, did not precipitate on the addition of two volumes of carbon to one volume of 2 per cent salt solution, but at six

TABLE II

| NO. | PATIENT | DATE | DILUTION  | CARBON CURVE |
|-----|---------|------|-----------|--------------|
| 13  | J. H.   | 9/18 | Water     | 5410000000   |
|     |         |      | 1.0% NaCl | 5443222110   |
| 14  | A. D.   | 9/18 | Water     | 5400000000   |
|     |         |      | 1.0% NaCl | 5442000000   |
| 15  | P. K.   |      | 1.5% NaCl | 4554321110   |
|     |         |      | 1.0% NaCl | 5542100000   |
| 16  | H. C.   |      | 1.5% NaCl | 5443211000   |
|     |         |      | 1.0% NaCl | 4431000000   |

months it was precipitated by 1.4 per cent salt but not by 1.2 per cent salt solution. This increase in sensitivity on standing is not sufficient in the case of the better solutions to prevent their being used for many months.

After the carbon has been added to the spinal fluid dilutions the readings can be made after standing overnight. Standing for a longer period has no effect on the curve obtained, as is shown by the readings taken at twenty-four hours and forty-eight hours in Table III.

TABLE III

| NO. | PATIENT | DATE  | HOURS | CARBON CURVE |
|-----|---------|-------|-------|--------------|
| 15  | P. K.   | 11/25 | 24    | 5542100000   |
|     |         |       | 48    | 5543100000   |
| 16  | H. C.   | 11/25 | 24    | 4431000000   |
|     |         |       | 48    | 4431000000   |

The solution as made is approximately 0.033 normal and is quite acid, various samples yielding  $P_H$  values by the quinhydrone electrode from 1.5 to 1.8. The influence of changes in acidity upon the sensitivity of the reaction was examined, the data of Table IV showing the influence of sodium carbonate and sodium hydroxide upon the precipitation of carbon by sodium chloride. The dilutions in Table IV were made by varying the concentration of sodium carbonate and sodium hydroxide in 2 per cent sodium chloride solution, using the 2:1 carbon: saline ratio as noted for the effect of salt concentration.

It will be seen that gradually increasing the amount of alkali added decreases the precipitation of the carbon solutions at first but finally the mixture again precipitates so that the addition of from 2 to 3 c.c. of 10 per cent

sodium hydroxide causes complete precipitation. The zone in which there is no precipitation is much wider for sodium carbonate than for sodium hydroxide. This stabilizing effect of the addition of alkali can be utilized to adjust oversensitive carbon solutions, so that they can be made suitable for use with spinal fluids. This effect is given in Table V, in which the curves obtained by the addition of varying amounts of sodium carbonate to the colloidal carbon solutions are compared with the corresponding gold curve. The milliliters of 10 per cent sodium carbonate solution added to 100 ml. of colloidal carbon are recorded as the second value in the hyphenated sample number, e.g. 26-0.2 indicates that 0.2 ml. of 10 per cent sodium carbonate was

TABLE V

\*Tuberculous Meningitis.

added to each 100 ml. of carbon Sample 26. It is evident that the addition of carbonate changes the character of the colloidal suspensions, so that it is possible to regulate the sensitivity in such a way that the carbon solutions will give curves very similar to those obtained with the gold sols.

In Table VI we have recorded the complete data for 54 spinal fluids. It will be noted that the carbon curves parallel those of the gold sol. In the normal spinal fluids there is as a rule precipitation only in the first two tubes with the carbon solutions, whereas slight changes occur in many of the gold dilutions. In the fluids obtained from patients suffering from meningitis, the carbon curves offer still more striking contrast to those obtained with normal fluids inasmuch as the former show a protective action in the first tubes of the series.

The observations recorded in the foregoing tables are such as to indicate that colloidal carbon solutions can be prepared which may be used as test media for spinal fluids. The development of a standard technic to cover all possibilities demands further experimentation with tests of many spinal fluids and many different carbon samples, and will be the subject of a future paper.

#### SUMMARY

Colloidal carbon solutions suitable for use with spinal fluids can be prepared by electrolysis between two carbon electrodes in a 0.033 N Chromic acid bath.

The optimum sensitivity and stability is obtained at 30 volts and 3 amperes.

The sensitivity of the colloid can be altered by the addition of small amounts of 10 per cent sodium carbonate solution.

The curves obtained with colloidal carbon solutions are shown to be similar to those obtained with the gold sols.

# A METHOD FOR THE SEPARATION OF THE PRINCIPAL CONSTITUENTS OF BILE<sup>2</sup>

ROBERT UNWIN HARWOOD, PH.D., MONTREAL, CANADA

## INTRODUCTION

QUANTITATIVE studies of the various constituents of bile have been a matter of considerable difficulty. Bile is one of the most complex and variable of body fluids. Whipple<sup>1</sup> has pointed out the wide variety of chemical compounds which may be found. Wide ranges in the concentration of any constituent may occur, in biles from the same species, in liver and in gallbladder bile from the same animal, and in addition, there is a marked difference in composition from one species to another.

Three of the most important groups of compounds which occur in all types are the pigments, the bile salts, and the sterols. The bile pigments include bilirubin, biliverdin, and other pigment derivatives. The bile salts form one of the most complex groups of compounds which occur biologically. Most animal biles contain some or all of the conjugated bile salts, combinations of glycine or taurine with cholic or deoxycholic acids. In addition, other bile acids may occur which are more or less characteristic of the species. Human bile, for example, may also contain lithocholic and chenodeoxycholic acids (Ingold<sup>2</sup>). By virtue of their complex nature certain bile acids have a marked tendency to form more or less stable complexes; deoxycholic acid with fatty acids forming the choleic acids; complexes have also been postulated with lecithin and with cholesterol. The bile sterols include free and ester cholesterol and probably also oxysterol.

The physical and chemical properties of these constituents are such that even a trace of one compound may interfere with the accurate quantitative estimation of another. Two examples of such interference will illustrate the difficulties.

The estimation of cholesterol has presented special difficulties. Not only is it necessary to prevent the removal of any bile salts during the extraction of cholesterol from a sample of bile, but also no pigments must be in the final extract. The presence of a tinge of yellow, due to the extraction of a trace of some pigment derivative as reported by several workers (McLure and Mortimer,<sup>3</sup> McMaster<sup>4</sup>), will interfere markedly with the accuracy of the final colorimetric estimation.

The Pettenkofer reaction has commonly been used for the estimation of

\*From the Departments of Biochemistry and Experimental Surgery, McGill University, Montreal.

Received for publication, September 12, 1933.

This work has been conducted under a grant from the Department of Experimental Surgery.

the bile acids although only acids of the cholic group may be thus estimated (Reinhold and Wilson<sup>5</sup>). Bile pigments again interfere with the production of the characteristic color and hence with the accuracy. Attempts have been made to overcome this defect by selective adsorption of the interfering substances (McLure, Vance and Greene,<sup>6</sup> Aldrich and Bledsoe<sup>7</sup>). The deficiencies of such methods have been pointed out by Gregory and Pascoe<sup>8</sup> who have advocated a monochromatic light to eliminate the interference in the final colorimetric estimation.

It is obvious that a greater accuracy could be expected in such colorimetric estimations if the desired constituents were separated completely from all other substances in the specimens of bile. Selective adsorption provides such a means of separation. Bile pigments, for example, have been adsorbed from urine on calcium carbonate, Hooper and Whipple,<sup>9</sup> and on barium sulphate (Cole,<sup>10</sup> Hunter<sup>11</sup>).

Few applications of such inorganic adsorptions to bile have been reported. McLure and others<sup>12</sup> adsorbed the bile pigments from duodenal contents on calcium sulphate. Wit<sup>13</sup> has recently studied the effectiveness of such compounds and found that ferric hydroxide and aluminum hydroxide completely clarified bile. Chiray and Cuny<sup>14</sup> have recommended neutral lead acetate for this purpose. Peoples,<sup>15</sup> more recently, has used calcium hydroxide to remove substances other than bile salts from bile prior to their estimation.

An extension of the principle of selective adsorption and preferential extraction should make it possible to separate several constituents from the same specimen of bile so that each might be determined. The method detailed below provides a simple method for the separation of the bile pigments, bile acids, and cholesterol from the same specimen of bile.

Briefly, the bile pigments are adsorbed on zinc hydroxide in aqueous solution. After many adsorbents had been tried this proved the most satisfactory since the reagent completely adsorbed the pigments at a slightly alkaline reaction. This is essential since the free bile acids precipitate out in an acid medium. Zinc hydroxide has the added advantage that it is a protein precipitant.

The greater part of the bile salts remain in the supernatant liquid. The fraction which is loosely adsorbed on the zinc hydroxide precipitate is removed by extractions, first with water, then with ethyl alcohol, while the pigments are not so removed. The latter solvent also extracts the cholesterol. In order to prove the completeness of extraction it was assumed that all bile acids were extracted similarly although, as Cuny<sup>16</sup> pointed out, the oxyacids give little or no color with the reagents for the Pettenkofer reaction. A negative test, especially using the more sensitive modification of an alcoholic solution of the bile salts with furfuraldehyde and sulphuric acid, was accepted as indicative of complete removal of the bile salts.

Repeated tests have confirmed the fact that the more common bile salts, at least, are insoluble in petroleum ether. The other common solvents such as chloroform, carbon tetrachloride and ethyl ether tended to extract traces of substances which produced a yellowish or brownish color with the reagents for

the Liebermann-Burchard reaction for cholesterol. This solvent was recommended by Elman and Taussig<sup>17</sup> for extracting cholesterol from whole bile. A negative Liebermann-Burchard test was accepted as indicating complete extraction of the cholesterol. The quantitative applications of this method of separation, especially with reference to the bile salt fraction, will be reported shortly.

#### METHOD

##### 1. Reagents.—

1. 0.5N potassium hydroxide.
2. Ten per cent zinc sulphate ( $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ ).

This is the concentration of alkali and zinc sulphate recommended by Somogyi<sup>18</sup> for the deproteinization of blood. Potassium hydroxide has been substituted for the sodium hydroxide since its carbonates and sulphates crystallize with little or no water of crystallization. The two solutions are related, however, as recommended, so that 10 c.c. of the zinc sulphate are neutralized to phenolphthalein by 10.8 or 11.2 c.c. of the alkali.

3. Ninety-five per cent and absolute ethyl alcohol.
4. Petroleum ether, boiling point 30-80° C.
5. Approximately 4N (22.4 per cent) potassium hydroxide.
6. Approximately 2N (14 per cent) potassium carbonate ( $\text{K}_2\text{CO}_3$ ).
7. Approximately 5N sulphuric acid, 1.39 c.c. concentrated sulphuric acid per liter.
8. Six per cent potassium hydrogen phosphate ( $\text{K}_2\text{HPO}_4$ ).

2. *Procedure*.—The quantity of bile required depends upon the constituent being determined. It has been found convenient to use such an aliquot of bile as will provide at least 25 mg. of bile salts or 0.5 mg. of cholesterol. This is usually achieved by using 1.0 c.c. or less of gallbladder bile or from 2.0 to 4.0 c.c. of fistula bile.

The quantity of bile must be carefully measured, preferably using a "to contain" pipette, into a 50 c.c. centrifuge tube. The pipette is rinsed two or three times with distilled water, using sufficient to bring the total volume to 10 c.c. Add 1 c.c. of the 0.5N potassium hydroxide, then add 1 c.c. of the zinc sulphate with gentle mixing. The contents of the tube are thoroughly mixed to obtain maximum adsorption of the pigment and precipitation of the protein. The tube is centrifuged for about five minutes. If the supernatant is not water clear, the addition of a few drops of the alkali followed by a similar amount of the zinc sulphate, will complete the adsorption. It is advisable to loosen any particles of the green precipitate from the upper portion of the tube by means of a fine stirring rod before the final centrifuging. The water-clear supernatant is decanted off into an Erlenmeyer flask.

To the precipitate is added about 9 c.c. of distilled water and the flocculent precipitate is stirred up thoroughly with a stirring rod which is rinsed off with about 1 or 2 c.c. of water. The tube is centrifuged and decanted off as before. This aqueous extract is added to the original supernatant. A second similar extraction is made with distilled water. These aqueous extracts remove not only a portion of the bile salts but also the excess zinc which should be removed by precipitation. Add 1 c.c. of 2N potassium carbonate to the combined aqueous extracts, mix and filter through a fat-free filter paper into a 125 c.c. Erlenmeyer flask. Wash the precipitate 2 or 3 times with small portions of distilled water to remove any bile salts.

The remaining portion of the bile salts and the cholesterol are removed by at least five similar extractions with 95 per cent ethyl alcohol. The first two are at room temperature while for the others the tube is placed in a water-bath at 60 or 70° C. for about five minutes with occasional shaking to prevent the precipitate from settling out. All of these alcoholic extracts are combined with the zinc-free filtrate forming the bile acid-cholesterol fraction.

The separation of the cholesterol from the bile salts presents little difficulty. Add 5 c.c. of 4N KOH to the bile salt-cholesterol extracts and evaporate to about 20 c.c. on the steam bath. This requires about thirty minutes which is sufficient to hydrolyze the cholesterol

esters but not the conjugated bile salts. At the end of this time 5N sulphuric acid is added to the first permanent turbidity due to the precipitation of free bile acids. The solution is then cleared by the gradual addition of 2N  $K_2CO_3$ , 2 c.c. in excess being added. Evaporate to dryness on the steam bath. The last traces of moisture may be removed by drying at 110° C. for not over thirty minutes. At least three extractions with 10 or 15 c.c. of petroleum ether, boiling up each time, and filtering from any solid particles if necessary are required. The petroleum ether extracts may be evaporated to dryness, taken up in chloroform and the cholesterol determined in the usual manner.

Bile salts may be separated from the potassium sulphate and carbonate by at least 5 extractions with absolute ethyl alcohol as above. The bile salts may be then estimated by some suitable procedure. A method to be published shortly has been developed to estimate the bile salts in this fraction.

The pigments may be readily removed from the precipitate. Add about 5 drops of 0.5N KOH and 2 c.c. of 6 per cent  $K_2HPO_4$  to the precipitate in the centrifuge tube. Stir thoroughly with a stirring rod in order to dissolve the pigment and to precipitate the zinc as the phosphate. Water or 95 per cent alcohol is then added slowly and with stirring to a volume of about 10 c.c. Place the tube in a hot water-bath for about five minutes with frequent stirring to favor solution. After centrifuging a clear green solution and a pale precipitate will be obtained. A second extraction with alcohol or water will remove the last trace of pigment.

#### SUMMARY

A simple method has been developed to separate the bile pigments, bile salts and cholesterol from the same specimen of bile. Each of these fractions may then be estimated without the interference of other constituents.

The author wishes to express his appreciation to Dr. J. B. Collip and Dr. D. L. Thomson of the Department of Biochemistry for their many helpful suggestions and criticism.

## A MODIFICATION OF THE LANGE COLLOIDAL GOLD TEST\*

---

FRED BOERNER, V.M.D., AND MARGUERITE LUKENS, A.B., PHILADELPHIA, PA.

---

SINCE the introduction of the colloidal gold test by Lange in 1912 many modifications have been reported. Nearly all of these changes have been in connection with the preparation of the reagent while the actual performance of the test has remained practically unchanged. The difficulties encountered in the preparation of suitable gold solutions accounts for the interest shown in this particular phase of the test. At best the preparation of the reagent is tedious, time consuming, and the solutions often fail to meet the necessary requirements of sensitivity.

We found that, by changing the method of diluting the spinal fluid, the test could be conducted with one-half the amount of reagent. This results in a saving of time and material as twice the number of tests can be performed with the same amount of reagent.

A series of parallel tests were conducted on each spinal fluid using the original method with 5 c.c. of reagent and the modification outlined below using 2.5 c.c. of reagent. A total of 12 fluids were tested, of which 5 gave typical Zone I (paretic) curves, 4 gave typical Zone II (syphilitic) curves, and 3 were negative. The reactions in the modified test were practically identical with those in the original test. A slight difference in the degree of reduction in a few of the corresponding tubes of each test was noted. This difference when present was at the beginning or end of the curves and not sufficient to alter the readings. Neither test proved to be more or less sensitive than the other.

To obtain additional proof that the amount of reagent used in the test could be varied, providing the fluid tested remained in the proportion, several lots of reagent were titrated for sensitivity by the method recommended by Ramsey and Eilmann.<sup>†</sup> In each case five separate titrations were conducted using 5, 4, 3, 2, and 1 c.c. of reagent with a corresponding reduction in the amounts of sodium chloride solution. The amount of reduction or sensitivity titer was exactly the same in all set-ups. This shows that the test can be conducted with any amount of reagent providing the test fluid is used in the same proportion as recommended in the original test. We feel, however, that the

---

\*From the Laboratories of the Graduate Hospital, University of Pennsylvania.  
Received for publication, September 21, 1933.

<sup>†</sup>Ramsey, Thomas L., and Eilmann, H. J.: The Preparation of Colloidal Gold Solution, *J. LAB. & CLIN. MED.* **18**: 298, 1932.

amounts recommended below are more practical than smaller amounts, due chiefly to the possible introduction of error when dilutions are made with less than one-tenth cubic centimeter of spinal fluid.

Although the results obtained in these tests would be expected, as there was no logical reason to the contrary, yet one is reluctant to modify in the least a well-established technic of such an important test without first obtaining proof that such a change would not in some way interfere with its accuracy.

We have since used the modified method outlined below routinely with very satisfactory results.

*Modified Colloidal Gold Test.*—

1. Place eleven chemically clean test tubes in a rack.
2. Into the first tube place 1.8 c.c. of 0.4 per cent sodium chloride solution and 0.5 c.c. in each of the remaining 10 tubes.
3. Add 0.2 c.c. of spinal fluid to the first tube and thoroughly mix. (We feel that the dilutions will be more accurate if 0.2 c.c. of fluid is diluted with 1.8 c.c. of salt solution rather than 0.1 c.c. of fluid with 0.9 c.c. of salt solution. If the latter is used, the 1 c.c. is not discarded from the first as directed in Step 4.)
4. Discard 1 c.c. from the first tube, then transfer 0.5 c.c. to Tube 2; mix thoroughly and remove 0.5 c.c. and place in Tube 3; continue until the tenth tube is reached and then discard 0.5 c.c. from this tube. The eleventh tube is used as a control.
5. Add to each tube 2.5 c.c. of colloidal gold solution.
6. Mix thoroughly and set aside for twenty-four hours. The readings are now made and recorded the same as in the original test.

CONCLUSION

1. The Lange colloidal gold test can be conducted with varying amounts of reagent providing the proportion of spinal fluid remains the same.
2. A modification of the test is recommended which requires but one-half the amount of reagent that is used in the original method.

# A DROPPER FOR PERFORMANCE OF FRAGILITY TEST OF RED BLOOD CORPUSCLES\*

HERBERT P. MACNEAL, M.D., PHILADELPHIA, PA.

IN THE performance of the red blood cell fragility test much difficulty was experienced in obtaining the desired dilutions of half percentage saline and distilled water when using the ordinary pipette for counting the number of drops.

To prepare the different strengths of saline solution by the drop method requires that the count of the number of drops of saline delivered to each test

Fig. 1.

tube be absolutely accurate and that all drops be equal in size. The use of the apparatus to be described has decreased the time necessary for performance of the test, has simplified the mechanical manipulations, and has increased the dependability of the results.

A large test tube (1 inch in diameter and 6 inches long) is heated in the Bunsen flame and pulled until the cross-section at the narrowest part is about one-eighth of an inch. The glass is cut at the desired point so that a two-inch section of small rubber tubing like that used in blood-counting pipettes may be

\*From the Temple University Hospital.

Received for publication, September 5, 1933.

pulled over it and firmly held by its own elasticity. A short section of glass tubing (about 1 mm. inside diameter) is attached to the lower end of the rubber tubing and an adjustable screw clamp is placed on the middle of the rubber tubing, completing the apparatus.

When performing the test, the apparatus is fastened in a ringstand and filled with the solution to be measured. The clamp is loosened until a drop of fluid forms on the tip of the glass nozzle every eight or ten seconds. If now the lower end of the rubber tube and the glass tip be pulled downward, putting the rubber tube on the stretch, the rate at which the fluid runs through the tube will increase roughly proportional to the amount of tension on the hose, the solution falling regularly from the glass tip in drops of uniform size. Since the tension on the rubber tubing is so easily controlled with one hand and the flow is so uniform, the drops can be very easily counted and the flow instantly stopped at the desired moment. Meanwhile the other hand remains free to slide the test tube rack and its tubes consecutively under the dropper until each tube has received its predetermined number of drops of liquid. Saline and distilled water may be measured through the same apparatus with only a rinsing between.

A few trials will show the operator just how much saline and how much distilled water is necessary for the test, so that file marks may be placed at the proper levels on the large test tube as a guide in conserving these substances. When not in use the apparatus should be rinsed, the clamp loosened, and the whole laid away for future use.

## SEDIMENTATION TIME OF BLOOD\*

---

### IMPROVED APPARATUS FOR ROUTINE OR RESEARCH TESTS

---

HERBERT P. MACNEAL, M.D., PHILADELPHIA, PA.

---

THE expense of the graduated test tubes usually employed in determining the sedimentation rate of blood has been saved by the use of the apparatus described, which uses ungraduated test tubes which are read against a graduated background. The technic of the test remains essentially the same as with graduated tubes.

The apparatus consists of two rectangular pieces of wood or other substance so fastened together as to form a baseboard upon which the test tubes stand and a backboard which supports the tubes and which bears a millimeter scale easily drawn with the aid of a straight edge and millimeter rule. One horizontal line is drawn 51 mm. above the plane upon which the test tubes rest, i.e., the baseboard. This line, which is marked "0," corresponds to the level to which the blood citrate solution appears in the tube when properly filled. The other mark-

---

\*From the Temple University Hospital.

Received for publication, September 5, 1933.

ings are made parallel to this "0" line at 10 mm. intervals. Finer lines may be drawn at 5 mm. intervals if desired. The completed scale (see Fig. 1) is used for determining the level between the cells and plasma in the tubes, which may be read directly to 5 mm. and to 1 mm. by interpolating between the nearest lines of the scale. Horizontal lines at millimeter intervals are easily ruled, but to us seemed unnecessary and confusing. The scale is most easily drawn on white paper with waterproof ink, carefully fastened to the backboard in the desired position and then covered with a piece of transparent celluloid film such as is used as a base in photography and radiography.

The test tubes are conveniently held in place with a continuous piece of soft brass wire which will not rust, become loose, or pull out. The lower row of wire loops should be placed about 7 mm. from the baseboard, instead of in the

Fig. 1.

position shown in the illustration. When in the lower position they do not interfere with reading the scale, yet securely hold the tubes—the first requisite of any test tube rack. As shown, this rack accommodates tubes having an inside diameter of 15 mm., or any tube of smaller caliber. This feature enables one easily to study the effect of tube diameters upon the rate of fall without the necessity of graduating the tubes themselves. A set of eyes in the upper edge of the backboard will hold the rack at eye level when fastened to hooks or nails at the proper height on the wall. A set of eyes on the side is useful in swinging the rack from vertical fixtures such as pipes or the corner of a projecting shelf where the rack would be placed more conveniently than if it were against the wall. Since the tubes are against the scale against which they are read and the rack is at eye level, there is a negligible error in making readings in this way. While the rack was made of quarter inch pine board, I should think Bakelite would be the ideal substance.

In our sedimentation tests the 11 mm. tubes were used for routine, although larger and smaller tubes were used experimentally. Regardless of the size of the tubes, they may be prepared in the same way. With a millimeter rule, a single file mark is made 7 mm. from the base upon which the tubes rest and another one 51 mm. from the base. The file mark is easily filled with colored crayon or India ink and the excess wiped off, leaving a mark clearly visible.

In use, 2 per cent sodium citrate is dropped into the tube until the meniscus reaches the lower mark and blood is added until the meniscus of the mixture reaches the upper mark. The amount of citrate should be carefully measured because any appreciable variation from this standard amount will change the rate of fall to a greater extent than will any of the other technical procedures.

### NOTE ON THE PROCEDURE IN THE KUTTNER-LICHTENSTEIN MICROCOLORIMETRIC METHOD FOR THE DETERMINATION OF ORGANIC PHOSPHORUS\*

---

DAVID GLICK, PH.D., NEW YORK, N. Y.

---

THE microcolorimetric method, developed by Kuttner and Lichtenstein<sup>1</sup> for the determination of organic phosphorus, involves digestion with sulphuric acid, aided by 30 per cent hydrogen peroxide of which the excess must be removed, and addition of sodium molybdate and stannous chloride to form a blue color. The only uncertain and tedious step in the procedure is the removal of excess hydrogen peroxide.

In the original method this was accomplished by adding water to the cleared digestion mixture, boiling down, adding more water, and repeating the process a number of times. From two to four hours are required to decompose the hydrogen peroxide completely, and almost constant attention is necessary. An alternative method, requiring little attention, consists of keeping the tubes in a hot water-bath for two or three days, and replacing the evaporated water from time to time.

The present modification eliminates both the tedious and time-consuming factors. It is carried out in a simple way as follows:

After the digestion mixture has been finally cleared (for some organic materials this may take a few additions of hydrogen peroxide with subsequent heating after each), it is digested for three minutes after the first white fumes appear. Care should be taken not to lose sulphuric acid by excessive fuming, since it has been shown<sup>2</sup> that, if the acid concentration in the final blue solution is less than 0.9 N, additional color is produced. Accordingly, the flame should be regulated so that white fumes appear in the bottom of the tube, but condense farther up.

---

Received for publication, September 19, 1933.

At the temperature of the boiling concentrated sulphuric acid, the three-minute period is sufficient to decompose the excess hydrogen peroxide. The excessive time required in the original procedure is the result of the relative stability of hydrogen peroxide at the boiling temperature of the dilute acid.

## A SIMPLE TECHNIC FOR FINDING COCCIDIOIDES IMMITIS\*

W. P. STOWE, M.D., SAN FRANCISCO, CALIF.

RECENTLY, while searching fresh moist preparations of sputum from a case of coccidioidal granuloma, for the characteristic spherical bodies, I found that they showed a strong iodine staining power. If enough Lugol's or Gram's iodine solution be mixed with the sputum or sinus tract pus to

Fig. 1.—*Coccidioides immitis*, iodine stain ( $\times 640$ ).

color the other cells a lemon yellow color, the coccidioidal bodies will take a rich brown tint within five minutes and can be located easily by the low power objective.

Having seen no reference to this simple trick, I offer it to those who have occasion to look for these organisms. A large amount of material can be searched very quickly, and fat droplets or air bubbles that are confusing, at least to those unfamiliar with the organism, can be quickly excluded.

Fig. 1 shows the strong contrast produced.

## THE ESTIMATION OF ETHYL ALCOHOL IN BRAIN\*

R. J. ABERNETHY, A.B., E. R. RUSSELL,† M.S., AND C. H. THIENES, M.D., PH.D.,  
LOS ANGELES, CALIF.

### I. ALCOHOL IN EMBALMED TISSUES

THE identification and quantitative estimation of ethyl alcohol in the embalmed body has heretofore been difficult, if not impossible. Yet tissues from embalmed bodies are often sent to the chemist with the statement that alcoholism is the probable cause of death, and the chemist is expected to establish the point. We, therefore, planned experiments in the hope of developing a dependable quantitative method, based upon the method of Gettler and Tiber.<sup>1</sup>

Briefly, the Gettler and Tiber method consists of a steam distillation of a weighed portion of the brain (500 gm.); an aliquot portion of the steam distillate is then treated with potassium dichromate and sulphuric acid, redistilled, and an aliquot of the resulting acetic acid distillate titrated against twentieth normal sodium hydroxide. The percentage of ethanol is then calculated in terms of the sodium hydroxide titration, 1 c.c. of twentieth normal sodium hydroxide being equivalent to 2.3 mg. ethanol.

Throughout, the procedure of Gettler and Tiber has been followed, except where modification has been necessary to accommodate the amount of tissue used, and where the purpose of the experiment required. Preliminary to the investigation of tissue, standard mixtures of formaldehyde, methanol, and ethanol were used. The concentrations of ethanol in these mixtures were approximately those found in brain tissue, viz., from 0.4 per cent to 0.6 per cent. The method of removal of methanol and formaldehyde is based on the ease of oxidation of these compounds to carbon dioxide and water. Acetic acid, the oxidation product of ethanol, is extremely stable.

Direct distillation of the mixture from dichromate and sulphuric acid was first tried. On titration the results were quite variable, and in most instances, the values were much higher than was warranted by the amount of ethyl alcohol present. It was assumed that the increased acidity above that for acetic acid was due to formic acid, and no qualitative estimation of the oxidation products was undertaken. This experiment was repeated with the introduction of a preliminary period of refluxing before distillation. Upon distillation and titration the results were in agreement with the amounts of ethanol present in the original mixtures. This was accounted for by the fact that in refluxing, the methanol and formaldehyde are oxidized to carbon

\*From the Los Angeles County Health Department, Bureau of Laboratories, Division of Legal Chemistry, and the Department of Pharmacology, University of Southern California.  
Received for publication, September 22, 1933.

†Deceased.

dioxide and water, while the oxidation product of ethanol, namely acetic acid, is stable in the oxidizing mixture. The above results were duplicated many times.

The time of refluxing was varied. It was found that from thirty to forty-five minutes at a slow boiling point was sufficient for complete oxidation.

The above procedure was then applied to brain tissue of rabbits. The animals ranged from 1.5 to 3.3 kilograms in weight.

Five rabbits were used for an estimation of a possible normal alcohol content of the brain. They were housed for a period of one week prior to use, and fed upon carrots, lettuce, and whole bran.

The animals were killed by the neck stroke, and the brain removed, placed in an agate mortar, and thoroughly macerated. The macerated tissue was then washed into a 2 liter flask to which were added 300 c.c. of distilled water, a few drops of mineral oil and 1 c.c. of saturated tartaric acid solution. The flask was then connected to a steam still fitted with a Cummings bulb, and 300 c.c. of distillate was recovered. The entire steam distillate was placed into a 500 c.c. flask to which 20 gm. potassium dichromate and 40 c.c. of concentrated sulphuric acid were added. The flask was connected to an upright spiral condenser and 250 c.c. of distillate recovered. One hundred cubic centimeters of this distillate were titrated against N/100 NaOH. The titrations never exceeded 2.5 c.c. of the standard solution. An aqueous acid control distillation carried out in the same manner gave the same titration figures. Due to the agreement in blank and titration of brain distillates, it was assumed for the purpose of the experiment that the brains were negative for alcohol.

A second group of 5 rabbits were given by stomach tube, ethyl alcohol at a dosage of 6 gm. of ethanol per kilogram weight. The alcohol solution was of the strength of average alcoholic beverages (brandy, 50 per cent). The animals were killed, at one, two, five, ten, and twenty-four hours after the alcohol administration and the brains analyzed for alcohol, to determine roughly the time for development of maximum alcohol concentration in the brain. Table I shows the results of the experiment.

A second group of 13 rabbits were given the alcohol solution in the same dosage (6 mg. per kg.). Five animals were killed after an interval of five hours and the ethanol content of the brain estimated immediately; 8 animals were killed and embalmed immediately, and the brain removed for analysis one hour later. Two more animals received half the above dosage (3 mg. per kg.) and were killed five hours later for analysis of their brains. Finally,

TABLE I

| RABBIT | TIME ELAPSED | PER CENT ETHANOL |
|--------|--------------|------------------|
| 4      | 1 hour       | 0.321            |
| 10     | 2 hours      | 0.325            |
| 11     | 5 hours      | 0.359            |
| 10a    | 10 hours     | 0.278            |
| 12     | 24 hours     | 0.0031           |

three animals received this latter dosage, were killed after five hours and were embalmed one hour prior to removal of the brain. Table II shows the results of the experiment.

A control group of 5 animals were then killed in the same manner and embalmed. Upon analysis of the brain tissue the results were in accordance with those which were determined upon fresh brain tissue of control rabbits, the figures checking closely with blank titrations.

#### SUMMARY AND CONCLUSIONS

By modification of the Gettler and Tiber technic, introducing a period of refluxing of the dichromate-sulphuric acid step in the procedure, formaldehyde and methanol may be completely removed, so that only the ethyl alcohol fraction, namely acetic acid, appears in the final distillate for titration. Rabbits were used for the experiments. It seems safe to conclude that by this method, quantities of alcohol of medicolegal importance can be determined in brains of embalmed rabbits, and probably of embalmed human brains.

#### II. A MODIFICATION OF THE GETTLER AND TIBER METHOD FOR TRACES OF ALCOHOL

In the routine analysis of human brains for alcohol in the laboratory of the Los Angeles County Health Department, wherein the method of Gettler and Tiber was employed, more than 100 brains were tested whose titration figure was 0.9 c.c. or less of 0.05N NaOH. Such brains were reported to the coroner as negative for alcohol. Recalling, however, that Gettler and Tiber found an average of 0.0015 per cent alcohol in normal brains by correcting for organic acids in blanks similarly obtained, an effort was made to modify the method to reduce the total titration instead of correcting for it. The first

|                                           |                  | 33                                      | 0.078            |

distillate from the brain contains alcohol and certain titrable organic compounds; the second distillate contains similar titrable substances in addition to the acetic acid, resulting from the oxidation of the alcohol. Gettler and Tiber calculated the normal alcohol present by subtracting the acidity of the first distillate from the acidity of the second distillate. The present study was based upon the supposition that the insertion of an alkaline distillation between

the first and second regular distillations would hold back the interfering materials. The procedure was as follows:

Five hundred grams of tissue was steam distilled to collect 800 c.c. After filtration, 300 c.c. was treated with 20 grams of potassium dichromate and 40 c.c. of sulphuric acid and distilled to collect 250 c.c. Fifty c.c. was titrated for the report to the coroner. When the titration figure for the 50 c.c. was 0.9 c.c. 0.05N NaOH, or less, the remainder of the steam distillate (500 c.c.) was treated with 50 c.c. of 3N NaOH or the equivalent amount of  $\text{Ca}(\text{OH})_2$  for the purpose of forming non-volatile soaps of contaminating organic acids. This mixture was steam distilled to collect 500 c.c., 300 c.c. was treated with dichromate and sulphuric acid and distilled to collect 250 c.c. and the entire distillate titrated. The figure for the reagent blank of 0.65 c.c. 0.05N NaOH was subtracted. One c.c. 0.05N NaOH is equivalent to 0.0013 per cent alcohol. This factor includes the correction of 90 per cent recovery in the acid distillation besides the corrections of dilution and conversion of acetic acid to alcohol.

Distillations from seven brains have been tested by the above procedure, with results as indicated in table III.

Before further work on the problem was undertaken, the paper by Gettler, Niederl, and Benedetti-Pichler<sup>2</sup> appeared, showing the average alcohol content of seven brains to be 0.0004 per cent, with a range of 0.00027 to 0.00055 per

\*Calculated for 250 c.c. of distillate.

cent. It will be seen that when  $\text{Ca}(\text{OH})_2$  was used to prevent volatilization of organic acids in the steam distillation process, the alcohol values for two brains by the titration method approached the values obtained by Gettler, Niederl and Benedetti-Pichler, using much more refined technic. The titration figures for two other brains by the  $\text{Ca}(\text{OH})_2$  method were so close to the blanks that calculations of percentage would have had no significance.

It is suggested that the figures for the  $\text{Ca}(\text{OH})_2$  distillation are lower than those for the NaOH distillation because of the lower volatility of the resulting calcium compounds.

Because present circumstances prevent further investigation of this type, and because of the closeness of the figures obtained by the modified distillation process with those by the more difficult procedure of Gettler and his

associates, the present results with the small number of brains are reported. It is believed that the method is useful for the determination of minute amounts of alcohol in human tissue.

The authors wish to acknowledge the helpful guidance and encouragement of Dr. R. V. Stone, Director of the Bureau of Laboratories, Los Angeles County Health Department.

## THE DIAZO REACTION FOR DETECTION OF CERTAIN LOCAL ANESTHETICS IN URINE AND IN TISSUES\*

W. E. GIBB, B.S., M.S., AND WILLIAM M. DEHN, PH.D., SEATTLE, WASH.

EGGLESTON and Hatcher<sup>1</sup> showed that procaine is rapidly destroyed by the liver. Thieulin<sup>2</sup> found that both it and its hydrolytic products were eliminated in the urine of animals. We have found that it can easily be detected in the urine a few minutes after injection in the tissues by application of Riegel's and Williams'<sup>3</sup> modification of the diazo reaction. In its most simple form one needs only to add in order a little sodium nitrite, acetic acid, and ammonia to observe the red or yellow formed, and compare the color with that of untreated urine. Any change of color is proof of the presence of procaine, etc., or their hydrolytic products such as meta or p-aminobenzoic acids, which because of contained amino groups also give colors with the reagent.

In a cadaver known to contain procaine, comminuted tissues made acid in reaction and then extracted with ether gave colors identical with the colors produced with the extracts from tissues made alkaline in reaction. This observation proves that procaine is hydrolyzed in the body, either before or after death. For this reason accurate quantitative analyses of tissues for procaine must involve the separation of procaine and its hydrolytic product, p-aminobenzoic acid.

In Table I are recorded data on the diazo reaction as applied to 1,233 specimens of urine examined in a hospital over a period of three months. All these patients had received medicine as administered in hospital practice, and only about 5 per cent of them had received procaine.

Seven of the patients showing apparent positive test for procaine, but not receiving procaine, were found to have gallbladder disease; these urines gave positive Van den Bergh tests for serum bilirubin. The other two patients did not return for further investigation. When apparent positive tests were indicated, the colors were not as distinct as in the tests following administration of procaine.

| Positive first hour                                          |    |  |                |       |       | 59       |
| Positive second hour                                         |    |  |                |       |       | 3        |
| Positive third hour                                          |    |  |                |       |       | 1        |
| Procaine negative (urine lost)                               |    |  |                |       |       | 1        |
| Not receiving procaine but giving apparent positive reaction |    |  |                |       |       | 9        |
| Negative urine                                               |    |  |                |       |       | 1,160    |

In all cases not showing a positive test during the first three hours there was evidence of impaired kidney function with some retention of urine. Three of these patients had a high blood urea and creatinine. Morning urine, which showed a high degree of color, showed no reaction or change in color in testing for procaine. As yet no specimens of urine except the seven mentioned above have given a test for procaine, except where procaine was given.

## SUMMARY

Riegel's and Williams' test is a quick and reliable test for procaine and other aminobenzoic acid derivatives used as local anesthetics, when excreted in the urine or when present in the cadaver. Over 1,100 specimens of urine of patients not receiving procaine gave negative tests, except that a few cases gave apparent test when gallbladder diseases were present. Hydrolytic products of procaine were found in the tissues of a cadaver.

## CAGE FOR MICE AND RATS\*

ALLAN W. BLAIR, AND EMMETT B. CARMICHAEL, UNIVERSITY, ALA.

THIS type of cage has been used by us for the past two years, and we feel that it possesses distinct advantages over other types of cages used heretofore. In our experience some of these advantages consist in the prevention of food and bedding pollution by the segregation of each in a different compartment, the ease and cheapness of construction, the greater accessibility of the animals, the ease of cleaning, the ease of observation of the undisturbed animal and the ease of transportation from place to place. The cage serves well for feeding experiments, breeding purposes, stock animals, and general experimental purposes. It is compact, economical of space, and may be

placed on a narrow shelf. Waste cotton is employed for bedding and it is placed in the upper compartment. If so desired, the food may be placed in the upper rather than the lower compartment.

*Dimensions.*—11.25 x 8.5 inches.

*Materials.*—Galvanized hardware cloth ( $\frac{1}{4}$  inch mesh) for body, door, removable floor, and as a guard around opening between the two compartments (to prevent bedding material from falling through into lower compartment); sheet zinc ( $\frac{1}{32}$  inch) for floor of upper compartment, card holder, and to form margin of door opening; sheet metal ( $\frac{1}{16}$  inch) for band at bottom of cage and door catch; heavy wire soldered to edge of mesh door (to provide additional strength and support); water container (6 inch test tube, single hole rubber stopper, glass tubing) fastened by detachable clips to side of body; enamel pan.

# DEPARTMENT OF REVIEWS AND ABSTRACTS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

**DIPHTHERIA, Precipitated Toxoid as an Immunizing Agent Against,** Baker, J. N., and Gill, D. G. *Am. J. Pub. Health* 24: 22, 1934.

A single injection of 1 c.c. of precipitated toxoid has rendered 100 per cent of 197 Schick-positive children Schick-negative. Similarly, 1,400 of 1,414 children, or 99 per cent, were Schick-negative when tested on an average of from two to three months after a single injection. The original immunity status was unknown. Observations on 16,289 inoculations revealed 8 with abscess formation. As a rule local or general reactions were not severe.

**ERYSPELOID, Among Workers in a Bone Button Factory Due to the Bacillus of Swine** Erysipelas, Mc Ginnes, G. F., and Spindle, F. *Am. J. Pub. Health* 24: 32, 1934.

Two hundred and ten cases of an erysipeloid condition occurred in a bone button factory among individuals handling cattle or hog bones. There was a close correlation with the handling of wet bone and occupations in which injuries were frequent. Repeated attacks of the disease were frequent, indicating that there was little or no local or general immunity produced by an attack. The bacillus swine erysipelas was isolated from one case and from samples of bone, bone material, and bone waste collected at various stages in the manufacture of buttons. For ridding the plant of infection the heating of all bones entering the plant in the soaking vats to a temperature of 144° F. for at least two hours is recommended.

**TUBERCULOSIS, Blood Culture in,** Penfold, W. J., and Butler, H. M. *Med. J. Australia* 2: 837, 1933.

In three out of twenty cases of tuberculosis it was possible to cultivate *Bacillus tuberculosis* from the blood by Lowenstein's method. In the cultures from one other case acid-fast organisms could be identified microscopically by means of smears made from the surface of the medium; but these cultures, though incubated for six months, failed to produce colonies visible to the naked eye. Subcultures from them likewise failed to grow.

The Lowenstein method of blood culture in tuberculosis is troublesome and time-consuming in execution and gives so few positive results that the authors cannot believe that it is destined to render any great service to the clinician in the diagnosis of tuberculosis.

**DIABETES, Insulin Resistance in,** Mac Bryde, C. M. *Arch. Int. Med.* 52: 932, 1932.

Attention is called to the frequency of occurrence of relative resistance to insulin in uncomplicated cases of diabetes mellitus.

Clinical studies of two cases of insulin-sensitive and three cases of insulin-resistant diabetes are reported.

In two of these patients resistance to endogenous insulin was apparently broken, an overdosage of insulin being followed by marked improvement in carbohydrate tolerance.

The clinical characteristics of the insulin-resistant type as distinguished from the insulin-sensitive type are outlined.

Reported cases of insulin resistance may be grouped as follows:

(a) Unexplained, such as the five cases reported in this paper. Insulin resistance is

usually of mild or moderate degree in this group. Hyperactivity of the suprarenal-sympathetic system is suggested as the cause of this type of resistance. Many of these patients might be termed constitutionally resistant.

(b) Infection.

(c) Destructive pancreatic disease.

(d) Disorders of other endocrine glands, particularly the thyroid, pituitary and suprarenal glands.

(e) Hepatic disorders.

(f) Miscellaneous conditions such as acidosis, coma, diseases of the skin and cardiac decompensation.

The value of determining the relative responsiveness to insulin for treatment as well as for further study of diabetes is emphasized.

**MYELOSIS, Aleukemic, Baldridge, C. W., and Fowler, W. M.** Arch. Int. Med. 52: 852, 1933.

Ten cases are reported in which a common feature was myeloid hyperplasia.

Two cases were ordinary instances of leucemic myelosis, except that in the course of each there developed an almost completely aleukemic period. In one case the aleukemic period was thought to be due to irradiation of the spleen; in the other, it was "spontaneous."

Four cases thought to be diffuse hyperplasia of the myeloid tissue were characterized by severe anemia, leucopenia, a few abnormal leucocytes, secondary hemorrhagic purpura, changes in the bones and extramedullary collections of myeloid cells.

Two cases were indistinguishable from ordinary multiple myeloma, except that the tumors were made up of myeloid cells instead of plasma cells. One case presented chemical changes sometimes seen in multiple myeloma of the plasma cell type.

In the last two cases extramedullary myeloid tumors were present without definite evidence of disease of the bone marrow.

**ANEMIA, Macrocytic in Disease of Liver, Van Duyen, J. 2nd.** Arch. Int. Med. 52: 839, 1933.

An introductory case illustrating the occurrence of macrocytic anemia in cirrhosis of the liver is briefly reported.

References from the literature show this to be a widely recognized syndrome.

Three cases of disease of the liver are reported in which personal study has confirmed the macrocytic character of the anemia.

Twenty-eight cases of hepatic cirrhosis were reviewed from the records of the Syracuse University Hospital. Macrocytic anemia was found in 5 cases, or 18 per cent.

The mechanism producing a macrocytic type of anemia is discussed. Diseases of the liver is given a place in this mechanism.

**SCHULTZ-CHARLTON TEST, Fischer, A. E., and Kojis, F. G.** Am. J. Dis. Child. 46: 1282, 1933.

From a study of this reaction as well as the calcium blanching test in 486 cases the authors conclude that:

The Schultz-Charlton test is specific for the rash of scarlet fever.

A 10 per cent solution of calcium gluconate will cause slight blanching in some early cases of scarlet fever in which a mild or moderately intense rash is present. This action, however, is not so constant or so persistent as that obtained with dilute scarlet fever antitoxin.

The actions of calcium and of antitoxin on the rash of scarlet fever are totally different.

The fact that calcium will blanch a rash does not in any way detract from the validity of the Schultz-Charlton test.

The Schultz-Charlton test, provided its limitations are understood, is invaluable in the early diagnosis of scarlet fever.

**MALARIA, A New Antigen for Henry's Reaction, Livierato, S., Vagliano, M., and Constantacato, G.** *Greece Med.* 31: 177, 1933.

The sac of a cuttlefish with its contents is cut up into small pieces and put into a sterile tube; 40 c.c. of sterile distilled water are added, and 0.02 c.c. of formalin. After twenty-four hours at room temperature, the supernatant fluid is pipetted off; it is kept in the ice chest for two months before use, and is shaken daily. It is diluted to make a slightly blackish fluid just before use. The results are the same as those obtained with Henry's ox-eye melanin.

**SYPHILIS, Blood Cytology in Treated and Untreated, Rosahn, P. D., and Pearce, L.** *Am. J. M. Sc.* 187: 88, 1934.

From a study of the blood cytology of 126 treated and 87 untreated syphilis patients it was found that:

Treatment causes a fall in the total white cell count, the platelet count, and the relative and absolute numbers of neutrophils and monocytes, and a rise in the relative and absolute numbers of lymphocytes, and per cent hemoglobin, from values observed in the untreated cases.

No significant differences were noted between the mean blood cell values of the primary and secondary untreated patients.

A marked anemia was the outstanding feature of the blood cytology in the untreated tertiary disease. This anemia was absent in patients whose treatment was begun in the tertiary stage.

No differences in the blood cytology of treated patients were noted when treatment had been begun in the primary, secondary or tertiary stages of the disease.

A monocyte-lymphocyte ratio higher than 0.55 was more frequent among untreated patients and a monocyte-lymphocyte ratio less than 0.55 was more frequent among treated patients than would be expected from random association.

In a group of persistently treated patients, repeatedly negative serology was more frequently associated with a monocyte-lymphocyte ratio less than 0.45, with lymphocytes higher than 1,350 per c.c., and with monocytes less than 700 per c.c.; and persistently positive serology was more frequently associated with a monocyte-lymphocyte ratio higher than 0.45, with lymphocytes lower than 1,350 per c.c., and with monocytes higher than 700 per c.c. than would be expected from random association.

The changes observed in the cytology of the treated patients as compared with the untreated patients were similar in direction and affected the same cells as the changes observed in the spontaneously regressed experimental disease as compared with the period of lesion activity. This similarity lends additional weight to deductions drawn from the experimental disease as applied to human syphilis.

**ANEMIA, Aplastic, Analysis of So-Called, Thompson, W. P., Richter, M. N. and Edsall, K. S.** *Am. J. M. Sc.* 187: 77, 1934.

Thirteen cases of "aplastic" anemia have been studied. In all, the disease was characterized clinically by a progressive decrease in the number of erythrocytes, leucocytes and platelets, a progressive hypocythemia. In all, evidences of attempted regeneration were noted in the peripheral blood.

The marrow revealed a wide variation in microscopic appearance. In only 1 of the 13 was the marrow aplastic. In 2 it appeared hypoplastic, in 2 it was morphologically normal. In the remaining 8 there was moderate to marked hyperplasia of one or more of the formative elements.

It is felt that many of the restrictions and limitations placed on the clinical and pathologic diagnosis of "aplastic" anemia should be removed and that progressive hypocythemia alone should be sufficient reason for making the diagnosis, provided leucemia can be excluded.

The lack of correlation between the blood picture and bone marrow morphology has been discussed. It is felt that examination of the peripheral blood may be, at times, no index as to the condition of the blood-forming apparatus. Specifically, progressive hypocythemia as observed in these cases is not, in itself, sufficient evidence on which to postulate the presence of aplastic bone marrow.

This strongly suggests that it is quite possible to have serious interference with the normal processes of development, maturation and delivery of blood cells without evident alteration in the cellular content of the marrow.

**B. COLI HEMOLYTICUS, Clinical Significance of, Niles, W. L., and Torrey, J. C. Am. J. M. Sc. 187: 30, 1934.**

Strains of *B. coli* possessing hemolytic properties are frequently isolated from human feces (31 to 45 per cent of stools). They are somewhat more often found and in larger numbers in feces from patients with disorders relating to the digestive tract.

There is no distinctive difference either as regards morphology or cultural characteristics in the hemolytic *B. coli* strains isolated from the stools of normal or sick people, although those from the former group have seldom exhibited any virulence.

The authors have been successful in relieving the symptoms of toxemia by autogenous vaccines. *B. coli hemolyticus* has thus been eliminated from the feces in 93 per cent of their cases. They have recurred in 3 per cent after one year or longer.

Vaccination is the only method for eliminating *B. coli hemolyticus* from the human feces which the authors have found effective.

**TISSUE, The pH of Formalin—A Factor in Fixation, Burke, F. V. Am. J. Path. 9: 915, 1934.**

The following formula is recommended as superior and giving excellent results with all staining methods:

|                     |         |
|---------------------|---------|
| Distilled water     | 75 c.c. |
| Commercial formalin | 25 c.c. |
| Pure pyridine       | 5 c.c.  |

**BRUCELLA INFECTION, A Study of the Opsono-Cytophagic Power of the Blood and Allergic Skin Reaction in, Huddleson, I. F., Johnson, H. W., and Hamann, E. E. Am. J. Pub. Health 23: 917, 1933.**

The studies conducted on citrated blood of human beings who were known to have had undulant fever in past years and shortly after recovery, who are actively infected, or who have no history of the disease, show that the in vitro activity of the polymorphonuclear cells in whole citrate blood for Brucella is an expression of immunity to Brucella and an indication of the progress toward recovery in active infection. The absence of or a low phagocytic activity obtained in conjunction with a negative allergic skin test is evidence of susceptibility to Brucella infection. Infection in an individual is indicated by a positive allergic skin test obtained with Brucella nucleo-protein in conjunction with negative or low opsono-cytophagic activity of the whole citrated blood for Brucella.

The technic followed by the authors is described below:

**Determination of Opsono-Cytophagic Power of Blood:** The method adopted for determining the opsono-cytophagic power of blood for Brucella is a modification of the Leishman-Veitch technic and consists of mixing equal quantities of a citrated (0.8 per cent) fresh blood and a heavy bacterial suspension of living organisms in small Wassermann tubes, incubating at 37° C. for thirty minutes, and subsequently making spreads and staining with

Hastings stain. The addition of a definite amount of sodium citrate prevents clotting of the blood and inhibits the action of Brucella opsonins which are present in the serum of many normal individuals.

*Preparation of Blood Specimen:* The blood specimens are collected in 5 c.c. amounts in glass vials in which has been placed 0.2 c.c. of a 20 per cent solution of sodium citrate in physiologic salt solution. The final dilution of sodium citrate in the blood is 0.8 per cent. The test should be conducted on the specimens within six hours after collection provided they are kept in a cool place. The polymorphonuclear cells in blood disintegrate very rapidly when it is kept warm for two or three hours. The specimens should be thoroughly shaken directly before mixing with the bacterial suspension.

*Bacterial Suspension:* The bacterial suspension is prepared fresh each day by suspending several loopfuls of the growth from a forty-eight-hour liver agar slant culture in sterile physiologic salt solution of P<sub>H</sub> 7. The turbidity of the suspension should give a reading of approximately 2 cm. when measured with the Gates apparatus. Suspensions of any of the three species of Brucella are suitable regardless of virulence.

*The Test:* Into clean small glass vials, such as are used for the agglutination or Kahn test, are placed 0.1 c.c. of the whole blood and 0.1 c.c. of the bacterial suspension. After mixing thoroughly, the vials are placed in an incubator for thirty minutes at 37° C. Certain strains of Brucella tend to become "fast" to ingestion by the cells after being transferred daily for many weeks. If a culture is being used daily for the test, it should be checked frequently for "fastness" to phagocytosis against whole citrated blood from a known immune person. Continuous agitation during the period of incubation tends to inhibit phagocytosis. Considerable sedimentation of the blood cells takes place during the incubation period. The cells should not be resuspended by shaking after the period of incubation. Directly after removing the tubes from the incubator, a small amount of sedimented cells is removed by means of a finely drawn capillary pipette to which is attached a small rubber bulb. A drop of the cells is placed at one end of a thoroughly cleaned and polished glass slide, and drawn across the slide by placing the end edge of another slide at such an angle that the spread thins out and terminates at or near the middle. In a spread of this type, most of the leucocytes may be found near the terminating edge of the spread. The blood film should be dried as rapidly as possible to prevent shrinking of the leucocytes. Rapid drying may be obtained by placing the slides in front of a small electric fan. A small heating unit from an electric heater, if attached to the front of the fan and operated simultaneously, will greatly increase the speed of drying.

*Staining Spreads:* The slides are placed face upward on a suitable rack and the spreads covered with 0.5 c.c. of Hastings stain. After an exposure of fifteen seconds, 1 c.c. of distilled water is added to the stain on the slide. At the end of ten minutes, the spread is gently washed from stain with distilled water and dried in front of an electric fan.

*Estimation of the Degree of Opsono-Cytophagic Activity:* The size of the organism in question and the marked degree of phagocytosis which occurs in cells from immunes has necessitated the employment of a different system of recording phagocytic activity from that which is commonly used in studies of this nature. In routine work, a total of 25 cells is counted in different sections of the spread and each cell is recorded as negative when no phagocytosis occurs, as slight when from 1 to 20 bacteria are seen in the cell, as moderate when from 21 to 40 bacteria are found in a cell, and marked when the number of bacteria in the cell is above 40. The bacteria are so numerous in those cells showing marked phagocytosis that it is impossible to count all of them.

It is realized that the foregoing method of measuring degrees of phagocytosis is only approximate. It was adopted after making thousands of examinations by different methods.

## REVIEWS.

---

Books and Monographs for Review should be sent direct to the Editor,  
Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

---

### Influenza, With Special Reference to the Part Played by Pfeiffer's Bacillus, Streptococci, Pneumococci, Etc., and the Virus Theory\*

**I**NFLUENZA, because of its terrific morbidity and mortality, is, without doubt, one of the most important of all epidemic diseases. It is natural, therefore, that the literature concerning it has reached literally enormous proportions with little evidence of slackening in the flood of contributions.

While there has accumulated as a result a tremendous amount of information, it is questionable if it has ever before been gathered and correlated in one place.

To organize, abstract, and summarize this information is the purpose of this study, the completion of which will require two volumes.

In the present ninth volume of the *Annals of the Pickett-Thomson Research Laboratories*, which constitutes Part I of the Sixteenth Monograph from this source, the nomenclature, and history, as well as the clinical character of influenza, its varieties, symptoms, diagnosis, prognosis, mortality, and epidemiology are considered at length and in some detail.

In Part II, to be issued, the study will be rounded out by a consideration of the bacteriology of the complications of influenza as well as of the pathology, treatment, and prevention of the disease.

When completed, the monograph will represent a comprehensive survey of the literature of the investigations of this disease, summarizing the information contained in over 4,000 papers and present as well an account of the author's researches during the past fifteen years.

Those familiar with the previous monographs from this source will undoubtedly receive the present one with equal interest and recognize it as a contribution of undoubted value.

The rôle of Pfeiffer's bacillus is considered at length, the authors presenting as their own conclusion the belief that, while not the primary cause of true influenza, this organism plays an exceedingly important rôle in the production of the dangerous complications so commonly encountered in this disease.

They emphasize the importance and necessity for symbiotic studies in future investigations, an avenue hitherto subjected to but little consideration.

Like many others, the authors are strongly impressed by the symbiotic importance of streptococci in influenza and the fact that *B. influenzae*, streptococci and pneumococci when growing together enhance each other's virulence. They believe that the pneumococcus, while without special significance in the direct etiology of influenza, plays an important secondary rôle and directly influences the course of the infection. The evidence concerning the *Bacterium pneumosintes* they consider as yet inconclusive.

While the studies concerning the rôle of a filter-passing virus in the production of influenza are as yet incomplete and sometimes at variance, the Thomsons believe that the results of more recent work are consistent with the view that epidemic influenza in man is caused primarily by a virus infection, although further intensive study is needed.

Although space precludes any survey in extenso of this publication, enough has been said to indicate the importance of this contribution to what has been and, to a great extent is, one of the most baffling problems of medicine.

## Die physikalische Seite des Blutgerinnungs problems und ihre praktische Bedeutung\*

MANY are the theories that have been set up to explain the clotting of blood, many are the studies that have been made to determine the chemical processes involved. Practically, it is well known that the physical surface with which the blood is in contact has much to do with the clotting. In the live normal blood vessels the blood does not clot, in contact with the tissues and most foreign substances it does clot. However, the speed and the completeness of the clotting process vary greatly according to the surface with which the blood is in contact. Paraffin greatly delays clotting, glass produces rapid and strong clotting. A smooth, polished surface lessens clotting, a rough surface favors clotting. A substance with a low surface tension decreases clotting, high surface tension favors clotting. How can these facts be used practically? In the production of antitoxin a strong clot is desired to favor the full separation of serum; in the clinical transfusion of blood clotting is not desired. To lessen clotting, the needle with which the blood is drawn should be polished on the inside quite as well as on the outside as a rough surface favors clotting. The blood should not be allowed to touch glass as glass favors clotting by its high surface tension. A layer of paraffin on the surface of the glass lessens clotting but also lessens visibility. Lampert has found that amber lessens clotting almost as well as paraffin and is transparent. He hopes to find some substance that can replace glass entirely and practically eliminate the danger of clotting. Amber is a natural resin and now with all our synthetic resins such a hope may be realized.

---

## Ergebnisse der medizinischen Strahlenforschung†

THIS stately sixth volume of 650 pages maintains the high standard set by the preceding volumes. Its 470 cuts are well selected and excellently printed on good paper. A wide range of subjects is covered as is shown by a few of the chapter headings: "Skin erythema and roentgen rays" by Alfred Reisner of Frankfurt. This is a study of the various factors in the production of erythema, such as the quality and quantity of the rays, the effect of divided doses, season of the year, etc. It has 44 cuts and about 220 references. "The roentgenotherapy of arthritis deformans," by Günther von Pannewitz of Freiburg. This is a study based on the treatment of more than 1,500 arthritic joints and experimentally induced arthritis in animals. It has 60 cuts and about 100 references. "Roentgen diagnosis in obstetrics" by Paul H. Schumacher of Giessen. This demonstrates how helpful the x-rays can be in obstetrics. It has 65 cuts and about 500 references. "The roentgenological demonstration of diverticula in the intestinal tract" by Ludwig Bayer and Hans Pansdorf. A rather complete monograph giving the anatomy, physiology, origin, clinical significance, and treatment. It has 77 cuts and about 300 references.

---

## Handbuch der biologischen Arbeitsmethoden‡

THIS part 412 of this mammoth work contains chapters on determination of the respiratory quotient in surviving tissues, the various forms of the Helm respiratory apparatus, measurement of the basal metabolism with the Simonson apparatus, and an apparatus for the analysis of gases from respiration chambers for men and animals.

\*Die physikalische Seite des Blutgerinnungsproblems und ihre praktische Bedeutung. (The Physical Aspects of the Clotting of Blood and Their Practical Significance.) By Heinrich Lampert. Georg Thieme, Leipzig, 1931.

†Ergebnisse der medizinischen Strahlenforschung. (The Results of the Medical Investigations of Radiation.) Band 6. Georg Thieme, Leipzig, 1933.

‡Handbuch der biologischen Arbeitsmethoden, Lieferung 412. By Emil Abderhalden. Urban und Schwarzenberg, Berlin, 1933.

### Stedman's Medical Dictionary\*

HOW can one review a dictionary other than by remarking on the number of new words that have been added and concluding with a sophistry on the rapid growth of the language of the medical sciences? This can be done briefly. Over a thousand words have been added since the last edition three years ago. The language is growing by at least one new word a day. But in this book one does find more, deserving of mention. It is to be found particularly in the preface to the first edition, written twenty-five years ago. In it, the author backed by his wealth of previous editorial experience classifies himself unequivocally as a purist in etymology and nomenclature. He states his reason for his general principles of selection of spelling, clearly and logically. In the earlier days of this particular dictionary this was an uphill fight, in which the editors of some of the leading medical journals offered no cooperation. However, as the author states, the general principles for which he has contended have gradually been adopted not only in the general medical literature but also in the other two outstanding medical dictionaries.

The volume is an authoritative reference dictionary, which possesses a distinct advantage in that it is still being edited by the man who started it and who has still been able to develop it along the same clear-cut lines on which it was started and without changes of policy which sometimes tend to confuse the general plan.

---

### Handbuch der Chemotherapie†

THIS is the first part of the great work on chemotherapy which proposes to gather up and present systematically all the work that has been done so far in this great field. This first part includes only the nonmetallic organic compounds, but it runs to 650 pages. It includes such important compounds as quinine, emetine, cod liver oil, germanin, chenopodium, salicylic acid, santonine, chaulmoogra oil, and hundreds of others. For all of the important ones it gives the chemistry, the preparations, the chemical derivatives, the pharmacology, the animal and clinical experiments, the uses and extensive references to the literature. For example, after 25 pages given to other chinoline derivatives, 84 pages are given to quinine and its derivatives with ten pages of references. Emetine gets 33 pages, chaulmoogra oil and similar unsaturated oils 35 pages, etc. It is a veritable mine of information.

### The Laboratory Diagnosis of Undulant Fever

THE disease first known as Mediterranean fever and now recognized as indistinguishable in its etiology from "Bang's abortion disease" in cattle, has well borne out the prophecy of Nicolle who said of it: "Mediterranean (undulant) fever is in the course of evolution and is tending to become chronic. It is a malady which, on account of its manifestation and chronicity, will become one of the most common and stubbornest diseases. . . . Mediterranean fever is a disease of the future."

The correctness of this forecast is reflected in the now relatively voluminous literature of Brucellosis, as the infections due to this group of organisms, the *Brucella*, is now generally termed.

Recent interest and the modern investigations of undulant fever began with the appreciation of fact, first suggested by the work of Evans<sup>1</sup> and the

later studies of Meyer and Shaw,<sup>2</sup> and corroborated by those of other workers, that the organisms in this group, whether of human, porcine, caprine, or equine variety are all alike pathogenic for man and widespread in their distribution.

Whether they are each separate species or simply varieties of a single species is still under discussion and, for the clinician, possesses practically only an academic importance.

The fact that all are pathogenic for man and responsible for clinical syndromes by no means always clear cut or readily recognized is a matter of definite clinical importance; but the problem thus presented to the practitioner is fortunately rendered relatively easy of solution through the proper utilization of various laboratory procedures which have been developed and which are now more or less generally available.

Brucellosis, or undulant fever, in man may be seen in four types: malignant, intermittent, undulatory, and ambulatory not always, however, clear-cut or readily distinguishable as the disease has a marked tendency to change its type as it progresses.

The ambulatory and undulatory forms, together with the chronic and sub-clinical infections, are those most often presenting diagnostic difficulties, as the disease has not infrequently been found to be the explanation of obscure periodical fevers, arthritis, and intestinal and abdominal disorders and has been confused with tuberculosis and typhoid fever.

Very early in the study of human brucellosis the value and diagnostic significance of agglutination reactions became apparent so that this method was for some time regarded as having a value equal to, if not even greater than, that of the Widal test in typhoid fever.

Many studies soon showed, however, that the clinical interpretation and significance of positive agglutination reactions with *Brucella* antigen suspensions were influenced by a variety of factors.

Probably no one has been more closely associated with the investigation of brucellosis, nor has become more familiar with all its phases than Huddleson, whose studies, indeed, are responsible for much of the information now available concerning this disease and who may well be regarded as one of the outstanding authorities on the subject, especially as concerns its laboratory study and diagnosis.

Huddleson's rapid slide method for the performance of the agglutination test, for example, has long since been recognized as a standard procedure and his recent monograph<sup>3</sup> presents in an admirable and thorough manner the present status of the laboratory diagnosis of this disease.

The procedures of value in the laboratory diagnosis of undulant fever are: the agglutination test, the allergic test, and the estimation of the degree of opsono-cytophagic activity, all of which are especially valuable when, as in the majority of instances, the detection of the organisms by culture has not been possible or feasible.

The determination of agglutinins, whether in the serum in the case of man, or in the serum or milk in the case of animals is a procedure of great utility

which, by means of Huddleson's rapid slide method may be carried out practically anywhere.

When the macroscopic test tube method is used it must be recognized that the result may be influenced by a variety of factors among which, as determined by the work of Fitch and his coworkers<sup>4, 5</sup> and of Henry and Traum,<sup>6</sup> the more important are:

1. Hemoglobin in the serum, causing nonspecific agglutination.
2. Heating serum to 56° C. or over, which lowers its agglutination titer, an effect also produced by storage of the serum.
3. Excessive antigen turbidity which tends to decrease the titer of the serum.
4. Formalin or tricresol as preservatives which retard and may even inhibit agglutination.
5. Insufficient incubation of the test.
6. Presence of agar in the antigen, which may cause nonspecific agglutination.
7. Presence of thermolabile strains in the antigen which may be agglutinated by negative serum and not by positive serum.

While the rapid method of Huddleson, devised particularly for the examination of cattle, may also be used for tests of human serum, it is important to emphasize that the results cannot be given a similar interpretation as a negative reaction, even when repeated, does not necessarily signify an absence of infection, nor does a positive reaction even in high dilution furnish proof of an active infection, as it may be the result of past infection, either clinical or subclinical, or the result of exposure to infective materials, as in the case of veterinarians, dairy and packing-house workers and the like.

The results of agglutination tests in man must always be considered in the light of the history and other confirmatory tests.

The demonstration of allergic reactions as a method of diagnosis in the human being has been studied by various workers, Burnet<sup>7</sup> using a culture filtrate and Giordano<sup>8</sup> a killed suspension.

The determination of the opsonocytophagic power of the blood as an index of brucellosis was introduced by Huddleson, Johnson and Hamann<sup>9</sup> and bids fair to be definitely useful.

From the correlation of all these methods very valuable and clear-cut information may be obtained which has been presented by Huddleson<sup>10</sup> in the tabular form (Table I).

TABLE I

| AGGLUTINATION TEST | ALLERGIC SKIN TEST | OPSONO-CYTOPHAGIC POWER   | STATUS TOWARD BRUCELLA |
|--------------------|--------------------|---------------------------|------------------------|
| 0                  | 0                  | 0 - 20% of cells slight   | Susceptible            |
| 0                  | +                  | 0 - 40% of cells marked   | Infected               |
| +                  | +                  | 0 - 40% of cells marked   | Infected               |
| 0                  | +                  | 60 - 100% of cells marked | Immune                 |
| +                  | +                  | 60 - 100% of cells marked | Immune                 |

The application of these methods to the future study of brucellosis in man will undoubtedly clear up many obscure clinical problems and add still more to the increasing understanding of this now widespread infection.

## CLINICAL AND EXPERIMENTAL

---

### THE FRIEDMAN RABBIT OVULATION TEST IN DIFFERENTIAL OBSTETRIC DIAGNOSIS\*

---

ARTHUR G. KING, M.D., M.S., NEW ORLEANS, LA.

---

ONE of the notable recent advances in medicine has been the development of the biologic tests for pregnancy based on the fundamental discoveries of Smith, Evans, Long, Simpson, Aschheim, Zondek, and others. In this country the original Aschheim-Zondek test has largely been supplanted by the simpler modification of Friedman.<sup>1</sup> The principles and technic are well enough known to need no further description here, but although the results of the original Aschheim-Zondek test have been analyzed by many authors, there has been no recent compilation and discussion of the Friedman test. And yet an understanding of the limitations as well as the value of this biologic method of diagnosing pregnancy is essential for its intelligent use by the many physicians to whom it is now available.

In addition to the new cases added here, the literature through March, 1933, has been thoroughly combed, and every report listed in the *Quarterly Cumulative Index Medicus*, with the exception of a very few in certain foreign languages, carefully analyzed. These have been studied for comparison of technic, percentage accuracy, the cause of false results, and the types of cases in which it has been used. A summary is presented in Table I.

In all, 5,225 cases have been presented by 34 authors, but for analysis sufficient details are given of only 4,515. The gross, uncorrected error is 3.9 per

Received for publication, September 13, 1933.

cent. The false negative findings have been divided into three sorts: 82 due to limitations of the test, 13 due to technical flaws admitted by the authors, and 54 that cannot be explained. The latter group, together with the 26 false positive findings, amount to 1.8 per cent.

A positive reaction is expected if a suitable rabbit is injected with a quantity of urine containing a sufficient amount of the prehypophyseal hormone. This hormone is generally considered to be elaborated with explosive suddenness shortly after fecundation. Positive tests have been reported as early as ten or twenty days after the known fruitful intercourse. In the author's series the earliest was in a woman with great irregularity of menses, who delivered a seven-pound child 260 days after the test was made. On the other hand, at least 48 cases have been reported (including 3 of this series) where early tests were negative, while later tests have proved correctly positive. The explanation may be that the prehypophyseal stimulation did not occur to the usual extent or else the eliminative threshold of the kidney was different than that usually found. In 7 cases reported, the test remained negative until the fourth or sixth month. Hence, the first limitation of the correctly performed test is that *a negative reading does not rule out early pregnancy.*

| King                            | RS-S                  | 86              | 1                            | 8.2%                                      |

In the differential diagnosis between *simple amenorrhea* and *pregnancy*, the author's series includes 40 cases, in all but 4 of which clinical diagnosis was difficult. There were three false negative responses at seven, twelve, and sixty days after the missed period, all later positive. There were 16 correct negative and 21 correct positive diagnoses, including two decisions between subinvolution and early pregnancy before the resumption of menses.

Once pregnancy is established the test will remain positive only as long as live chorionic tissue is in biologic contact with the mother. This must be borne in mind in using the test to diagnose abortion or intrauterine death. There are 107 such cases available for comparison. Of 14 *threatened abortions*, all gave positive reactions except 2 of the author's 5 cases. Both of these began bleeding at three months' gestation; from 5 to 8 c.c. of urine were used and the tests were read in twenty-four hours as negative; in both the bleeding was controlled and the pregnancy continued, positive readings being obtained subsequently. It is suggested that a sudden diminution in the amount of prehypophyseal hormone may have accounted for both the threatened abortion and the negative reactions.

Of *incomplete abortions* the literature describes 37, of which 20 gave positive reactions and 17, negative, in the latter group falling the author's 5 cases. Unfortunately the condition of the placenta is not stated in most of the reports. Two of the cases in the present series deserve some mention; one was seven months postpartum, the other twelve months, and each had bled for some two months previously. The tests were negative, and the pathologist's reports were "placental polyp" and "infected products of conception." Whether these women became pregnant subsequent to their deliveries and then aborted is not known.

In *complete abortion*, of which there are 39 cases, the same conditions hold which apply to the puerperium, namely that from twenty-four to seventy-two hours after delivery either a negative or a positive response may be expected.

*Missed abortion* may be divided into those before the fourth month and those after. Of 8 early cases in the literature, including one of the author's, all gave negative responses. After the fourth month death of the fetus may take place independent of damage to the placenta or its hormone capacity, and hence it is not surprising that Wilson and Corner<sup>8</sup> and Schoeneck<sup>18</sup> each report two positive reactions. A. Brouha<sup>10</sup> obtained two negative reactions, and Ware and Main<sup>27</sup> one. The author has four to add. In three, fetal death between the sixth and seventh month was diagnosed clinically, but positive reactions were obtained seven, seventeen, and thirty days, respectively, after the cessation of fetal movements. In the fourth case a five months' fetus had been dead three months and the rabbit response to the urine was negative. Thus a second limitation of the test is that a *positive reaction does not rule out death of the fetus*.

In *ectopic pregnancy* the test again must be used with discrimination. A positive reading indicates that live chorionic tissue has been in existence within the last seventy-two hours; a negative test means little. Of 57 ectopic pregnancies reported, only 41 gave positive reactions, of which 2 are added in this series. It may be assumed that in the others either the hormone concentration was not sufficient or else the chorionic tissue had been long dead.

On the other hand, in hydatid mole and chorionepithelioma perfect satisfaction is expressed in all reports.

*Cancer* of the uterus, while occasionally giving a positive Aschheim-Zondek test, is usually reported as giving a negative Friedman reaction. One case in this series was negative. But another woman, aged thirty-eight, who had had her last child four years previously and had been bleeding irregularly for two years, passed some tissue, which from description might have been a mole. Two weeks later her Friedman test was positive. She was curetted, and the removed tissue diagnosed by the pathologist as "acanthoma" (squamous cell carcinoma). Two weeks later the Friedman test was again positive. She had a stormy convalescence but recovered, and two months later appeared to be in fair health. This case is presented as the only false positive in the series. The literature includes two other cases of carcinoma which gave positive, although atypical, responses.

In patients of obese habitus it is often difficult or almost impossible to differentiate *fibroids* or *ovarian cyst* from *pregnancy*, and where amenorrhea supervenes the Friedman test becomes particularly valuable. In this series there were 13 such cases of amenorrhea where the physician was frankly doubtful of the diagnosis and the test proved subsequently to be correct: 4 at two months, all negative; 5 at three months of which 1 was a case of pregnancy; and 4 at four months of which 2 were cases of pregnancy.

Of the greatest importance is learning of the existence of *pregnancy* in the presence of a *fibroid* or an *ovarian cyst* before laparotomy. In 6 cases in this series amenorrhea led the gynecologist to use the Friedman test before operating; four were correctly negative, and two correctly positive. In one of these two cases hysterectomy for fibroids was postponed until term; in the other removal of a dermoid cyst was not done until pregnancy had advanced to a point where the safety of the fetus was not threatened.

Other differential diagnoses in this series consisted of: menopause against pregnancy, pelvic inflammatory disease against pregnancy, and finally a case of menorrhagia in a girl of 18 (with a negative test) later shown to be puberty hyperplasia. Table II summarizes the cases in this series in which, with a few exceptions, the test was used to aid the author or other physicians to decide between several possible diagnoses.

It must be borne in mind that many of the false results may have been due to the method of performing the test. Seven different technics with minor variations are described in the literature. These are: that of Friedman and Lapham<sup>2</sup> ("FL"), where 5 c.c. of urine are injected three times a day for two days and the ovaries examined in forty-eight hours; that of Magath and Randall<sup>4</sup> ("MR") who give 15 c.c. and operate in thirty hours; that of Reinhart and Scott<sup>20</sup> ("RS") where a single injection of 5 c.c. is followed by examination in twenty-four hours; that of Wilson and Corner<sup>8</sup> ("WC") who laparotomize the animal in sixteen hours after a 5 c.c. injection; that of Schneider<sup>21</sup> ("S") who uses a larger dosage and waits forty-eight hours; that of A. Brouha<sup>10</sup> ("B") who opens the rabbit before injecting 5 c.c. and makes a final reading in twenty-four hours; and that of Wood<sup>16</sup> ("W") who laparotomizes first, gives 10 c.c., laparotomizes in twenty-four hours, and if negative gives another 10 c.c. and makes a final reading the next day.

The experience of men working with hormone reactions in lower animals indicates that frequent small injections of endocrine substances is far more effective than a single large dose. Friedman and Lapham's 92 cases without an error tends to confirm this observation. While Wilson and Corner obtained excellent results with sixteen-hour readings, many workers including the author have found that the reaction frequently does not become positive until between the twenty-fourth and forty-eighth hour. It is for this reason that although Reinhard and Scott's technic was used at first, in the latter cases of this series 10 or 12 c.c. in a single injection was followed by laparotomy in forty-eight hours as the most desirable routine.

TABLE II

SUMMARY OF 103 TESTS ON 86 WOMEN FOR DIAGNOSIS OF CHORIONIC TISSUE

|                                       | CASES    | POSITIVE | NEGATIVE |

| P.I.D.                                | 2        | 0        | 2        |
| Menorrhagia                           | 1        | 0        | 1        |

It is not unlikely that the breed of rabbit and the climate or season determines whether or not ovulation is quickly produced. The size of the rabbit is of equal importance. The lower limits as given by most authors are 1.5 kg., ordinarily three and one-half months of age. Adult rabbits are widely used after proper isolation even from other females. While Davis<sup>12</sup> considers fourteen days sufficient (but reports 4 false positive reactions) twenty-one to twenty-eight days is usually held to be the minimum. Death of the rabbit from a toxic factor in the urine is reported by six different authors as occurring in 2.7 per cent, 2.7 per cent, 5.8 per cent, 5.8 per cent (this series), 8.9 per cent, and 12 per cent. The cause of death, be it too acid or too cold a urine, or some poisonous substance has not been determined. Simple anaphylaxis, however, seems to have been ruled out.

As Snyder and Wislocki<sup>24</sup> have pointed out, the Friedman test is specific for the human female, and hence is not applicable to veterinary purposes. Ignorance of this fact recently led a well-known gynecologist to condemn the test in general for its failure to indicate pregnancy in three of his mares. On the other

hand the work of White and Severance<sup>9</sup> shows that in other respects the test is not as delicate as that of L. Brouha on male mice.

Finally there must be considered what constitutes a positive reaction. It is agreed that a translucent follicle, without color, is a negative response. Wilson and Corner<sup>3</sup> using a sixteen-hour technic describe a freshly ruptured, bleeding, red follicle as a true positive, and warn against a small, dark brown, rather conical body occasionally seen. Most authors look for a large, rounded, purplish corpus hemorrhagicum. Buettner<sup>22</sup> reports as a true positive a large pale unruptured follicle with tiny red flecks. Laparotomy within a week of three such observations showed the structures to have formed true corpora lutea. Grant<sup>14</sup> also observed such a follicle in one case which he reported as positive. Definite decision can be made by microscopic examination which will reveal beginning luteinization. Gustafson and Banks<sup>20</sup> report 5 cases grossly negative but correctly positive after histologic study. In the author's series a similar instance is recorded.

The cause of false positive responses is still to be worked out. Table III summarizes the false positive cases according to the cause or the diagnosis. Aside from the technical errors in handling the rabbits, any condition which might cause stimulation of the anterior lobe of the pituitary gland might be expected to cause a development of *prolan* which may be reflected in a positive rabbit reaction. Kraus<sup>35</sup> reports that an increase in *prolan* may be the result of elevated intracranial pressure. Germ cell tumors, pituitary gland tumors, compensatory hypertrophy of the pituitary gland, must all be considered.

The Friedman test for the diagnosis of pregnancy or its products is rapidly becoming a part of the physician's equipment along with the Wassermann test, agglutination reactions, and the leucocyte count. But it must retain its proper relationship to history taking and physical diagnosis. An interesting experience of one of the leading gynecologists of the country emphasizes its usefulness: his

TABLE III  
TABULATION OF FALSE POSITIVE REACTIONS

|                      |   |                   |

| Carcinoma            | 3 | Grant, et al.     |
|                      |   | Buettner          |
|                      |   | King              |
| Unexplained          | 7 |                   |

diagnosis of a case was that of a prolapsed twisted ovarian cyst, while his assistant was convinced that the patient had a recently ruptured ectopic pregnancy. The Friedman test was positive; laparotomy revealed on one side the tubal pregnancy and on the other side a small cyst which had prolapsed into the culdesac and which he had felt. But on the other hand, teachers in all branches of medicine find that their students, instead of training themselves to detect

pregnancy by their five senses, depend on a rabbit test to make the diagnosis. This test, however valuable, should never become popular at the expense of the *Tactus cruditus*.

### CONCLUSIONS

1. The results of 103 Friedman rabbit ovulation tests on 86 women are reported and discussed.
2. The literature to date is reviewed. Of 4,500 cases, the gross error has been 3.9 per cent; the corrected error, including the 26 false positive readings, amounts to 1.8 per cent.
3. The test is a valuable aid in differential diagnosis, provided its limitations are recognized.
4. A positive test indicates usually, but not always, the presence of live chorionic tissue. It may not become positive until pregnancy is well advanced, and if positive may not necessarily mean that the fetus is alive.
5. The test should assist but not supplant the usual diagnostic technic.

## THE RELATIONSHIP BETWEEN THE CORONARY BLOOD SUPPLY TO EXPERIMENTALLY PRODUCED VENTRICULAR LESIONS AND THE RESULTING ELECTROCARDIOGRAPHIC ALTERATIONS\*

DAVID I. ABRAMSON, M.D., J. HAMILTON CRAWFORD, M.D., AND  
GEORGE H. ROBERTS, M.D., BROOKLYN, N. Y.

IN A RECENT publication<sup>1</sup> the authors reported the electrocardiographic changes following ventricular myocardial lesions produced by the electric cautery. Particular attention was directed to the R-T segment and T-wave alterations resulting from definitely placed lesions, the localization of which was related to certain electrocardiographic characteristics as classified by Parkinson and Bedford.<sup>2</sup> It was found that cauterization of the anterior surface of the left ventricle gave curves of the T<sub>1</sub> type while a similar lesion of the posterior surface of this ventricle and of any portion of the right ventricle (except at the base anterior where no change was observed) resulted in curves of the T<sub>2</sub> type. Substantially similar results have been obtained recently by Haney, Borman and Meek<sup>3</sup> who investigated the changes in the R-T and S-T segments of the electrocardiogram in dogs in which the myocardial lesions were produced by radon implants.

\*From the Department of Physiology, Long Island College of Medicine.  
Received for publication, October 19, 1933.

This report is concerned with the relationship between the blood supply (as from the right or left coronary artery) to well-defined ventricular areas damaged by the electric cautery and the resulting electrocardiographic alterations. In a series of twelve cats, the coronary arteries were injected, by a method previously described,<sup>4</sup> and the vessel distribution, with respect to the damaged areas, studied in detail.

TABLE I

COMPARISON BETWEEN THE SITE BURNED, THE TYPE OF CURVE PRODUCED AND THE BLOOD SUPPLY

| NO. | SITE BURNED      | TYPE           | LEFT CORONARY | RIGHT CORONARY | MOSTLY LEFT CORONARY | MOSTLY RIGHT CORONARY |

RESULTS (TABLE I)

*Anterior Surface of the Left Ventricle.*—Two specimens (No. 3 and No. 30) were studied, in both of which the lesion had been produced at the apex and a T<sub>1</sub> type of curve obtained. In each instance the whole of the damaged area was supplied by the left coronary artery.

*Posterior Surface of the Left Ventricle.*—Six hearts, in all of which the resulting curve had been of T<sub>2</sub> type, were injected. In three the lesion was at the apex. Of these the left coronary artery supplied the whole of the injured area in two (No. 6 and No. 34) and the greater part of it in the third (No. 31). In the other three, the damage was at the base, the left coronary being the principal supply in one (No. 33), the right coronary in another (No. 7), while both played an equal part in the third (No. 35).

*Anterior Surface of the Right Ventricle.*—One heart (No. 32), in which a lesion had been produced at the apex and a T<sub>2</sub> type of curve obtained, was studied. The left coronary artery was the principal supply to this area.

*Posterior Surface of the Right Ventricle.*—This series consisted of three hearts, in which all of the curves were of the T<sub>2</sub> type. In one instance (No. 36), the damaged area was situated at the apex with the left coronary artery as the chief source of supply. In the other two, in which the lesions were at the base, the right coronary artery supplied the whole region in one (No. 38) and the greater part of it in the other (No. 37).

To summarize: It was found that in the two experiments in which a T<sub>1</sub> type of curve was obtained, the damaged site was supplied in whole by the left coronary artery. In the instances in which a T<sub>2</sub> type of curve resulted, the coronary distribution varied considerably. The area involved was sup-

plied wholly by the left coronary artery in two cases and in great part in four others. In the remainder, the right coronary artery supplied all of the cauterized region in one, was the main supply in two, while in another both vessels appeared to be of equal importance.

#### DISCUSSION

Barnes and Whitten<sup>5</sup> found that in infarcts of the anterior portion of the left ventricle, either alone or combined with a similar lesion at the apex, curves of the  $T_1$  type were produced; whereas in those of the posterior surface, with or without involvement at the apex, the tracings were of the  $T_2$  type. They believed that it was probably more than a coincidence that the plane of division which decided the type of electrocardiogram should follow the average plane of separation between the blood supply from the right and left coronary arteries. Despite this they suggested that it was the site of the lesion rather than the particular blood supply which determined the changes in the R-T interval, but that the site would usually indicate the artery involved. Bell and Pardee<sup>6</sup> analyzed five cases of their own and seven of Levine's series<sup>7</sup> and found that thrombosis of the left coronary artery was associated with changes of  $T_1$  type, while occlusion of the right coronary artery gave tracings of  $T_2$  type. They stated: "We therefore feel that in the absence of bundle-branch block, the electrocardiogram may be used in localizing the thrombus in either the right or left coronary system. We cannot offer any particular explanation for this relation between the vessel occluded and the particular T-wave that is inverted." On the other hand, Gilchrist and Ritchie,<sup>8</sup> as a result of a study of two cases of their own and a large series from the literature, concluded that changes in the R-T segment were strong presumptive evidence of myocardial infarction, but they did not believe the data available sufficient to warrant the view that the form of the electrocardiographic change could be considered a definite localizing sign of the infarct. Barnes and Mann<sup>9</sup> investigated the question in dogs surviving for varying periods, electrocardiograms being taken at intervals until death, when autopsies were performed. These workers tied off branches of the left coronary artery, supplying the posterior surface of the left ventricle, and obtained  $T_1$  type of curves, ligation of the right coronary artery resulting in  $T_2$  type. When one considers that a  $T_1$  type was obtained when the left ventricle was infarcted and a  $T_2$  type when a similar lesion was produced in the right ventricle, the fact that in the dog the left coronary artery supplies the whole of the left ventricle and the right coronary, nearly the whole of the right<sup>10</sup> might assume some importance in establishing a relationship between the type of RS-T alteration and the blood supply. Despite their findings, these authors do not consider the latter to be the determining factor, since they state that in man the electrocardiographic changes following acute infarction of the posterior basal portion of the left ventricle are constant regardless of whether this region is supplied by the right or left coronary artery. Wilson and his collaborators,<sup>11</sup> on correlating the form of the electrocardiogram with the location of the infarct in the human heart, state that the  $Q_1T_1$  type is usually asso-

ciated with a lesion of the anterior surface of the left ventricle, the  $Q_3T_3$  with one of the posterior surface. In some instances, however, lesions of these sites did not produce any characteristic change in the electrocardiogram. Fowler, Rathe and Smith<sup>12</sup> in a series of survival experiments in dogs, ligated small branches of the coronary arteries, both right and left, and found mainly T-wave changes. They were unable to correlate the location of the infarct and the type of electrocardiogram produced. Our results in the cat show that on the anterior surface of the left ventricle, the blood supply was always from the left coronary artery, and the electrocardiograms, following the production of localized lesions, were of the  $T_1$  type. Over the entire surface of the heart posteriorly,  $T_3$  types of curves were obtained, despite marked variations in blood supply. When one studies the relationship of all the  $T_3$  type of curves to the blood supply of the damaged areas without consideration of the region of the heart involved, the results appear grossly inconsistent. This view is further substantiated by an examination of the normal coronary distribution in the cat. In a recent study dealing with the latter,<sup>4</sup> it was found that posteriorly, in 65 per cent of cases the right coronary artery supplied all of the right ventricle and varying portions of the left ventricle, ranging from a small strip adjoining the posterior interventricular sulcus to almost one-half of the left ventricle. The remainder of this ventricle received its supply from the left coronary artery. In the other 35 per cent of cases the left coronary artery supplied posteriorly all of the left ventricle and the adjoining part of the right ventricle, while the right coronary in these hearts supplied only a small portion of the right ventricle.

In view of these anatomical observations we believe that the coronary distribution in the cat resembles that in man to a greater degree than does that in the dog. Although on the anterior surface of the heart, the subbranches of the right and left coronary arteries show a generally similar arrangement in all three, posteriorly there are some marked differences. In man, according to Gross<sup>13</sup> and also Barnes and Whitten,<sup>5</sup> the right coronary artery in the majority of cases gives off a posterior descending branch which extends down the posterior interventricular sulcus; the right coronary artery, itself, continuing on to the left ventricle to supply a considerable part of the latter adjacent to the sulcus. In these cases the circumflex branch of the left coronary plays an unimportant rôle in supplying the posterior surface of the heart. In a small percentage of cases, the situation is reversed, the circumflex reaching the posterior sulcus and continuing down in it, while the right coronary artery terminates soon after it reaches the posterior surface of the right ventricle. In these instances, posteriorly the whole of the left ventricle and the adjoining portion of the right are supplied by the left coronary artery. In the dog, according to Moore<sup>10</sup> the right coronary artery never reaches the posterior interventricular sulcus, but ends at some point between it and the right border of the heart. In all cases, the circumflex division of the left coronary artery proceeds down the posterior sulcus as the posterior descending division, and along with its other branches, supplies the whole of the left ventricle posteriorly. In man, the septum in its basal two-thirds is supplied by penetrating branches of the anterior and posterior descending arteries, subdivisions usu-

ally of the left and right coronary arteries respectively. The apical portion is supplied entirely by twigs from the anterior descending artery. In the case of the dog, branches of the septal division of the left coronary artery anastomose with penetrating vessels from the anterior and posterior descending arteries, the whole of the septum thereby being supplied by the left coronary artery. In the cat, in the majority of cases, the septum receives its supply from penetrating branches of both right and left coronary arteries, while in the remaining hearts, wholly from branches of the latter.

The R-T segment alterations associated with myocardial damage after blood vessel occlusion or direct injury are, we think, the expression in a limb lead of a monophasic variation of the demarcation current set up in the heart as the result of a potential difference between the injured and the adjacent uninjured areas. One should not expect that thrombosis of a particular coronary artery, per se, could produce the definite change observed in the electrocardiogram in coronary thrombosis. Only in the case of a constant blood supply would a characteristic change in the electrocardiogram be related to the occlusion of a particular artery. In our experiments on the cat, the blood supply (as to right or left coronary arteries) to the posterior surface of the heart varied markedly, and still on cauterization of any portion of this site a  $T_2$  type of curve was obtained in every instance. When we consider as well that the anatomical studies have pointed to a close resemblance between the coronary blood supply in man and that in the cat, it strengthens our belief that in the former it is hazardous to diagnose a thrombus in one or the other coronary vessel in a  $T_2$  type of curve. With a  $T_1$  type there appears to be every probability that the lesion is located in the left coronary artery. The final decision on this question in man must await the careful study of a sufficient number of hearts in which the electrocardiographic and pathologic data have been investigated and correlated. On the other hand, since all authors agree that infarct of the right ventricle is rare, it seems to us probable that a definite  $T_1$  type of electrocardiogram indicates a lesion of the anterior surface of the left ventricle and a  $T_2$  type one of its posterior surface.

#### SUMMARY AND CONCLUSION

The relationship between the blood supply (as from the right or left coronary artery) to experimentally produced ventricular lesions and the resulting electrocardiographic alterations was investigated in a series of injected cats' hearts.

Although on the anterior surface of the heart, there appeared to be a relationship between the curves and the blood supply, on the posterior surface, both of the right and left ventricles, tracings of  $T_2$  type were produced, whereas the blood supply to these areas varied markedly.

The results support the view that the characteristic T-wave changes are not constantly related to the occlusion of a particular coronary artery.

## THE EFFECT OF HYPERPYREXIA UPON THE PHOSPHORUS PARTITION OF WHOLE BLOOD IN PARESIS\*

DE LESTER SACKETT, B.S., AND A. WILLARD TURNER, A.B., ELGIN, ILL.

RECENT investigations have shown there are changes in the amount of the various phosphorus fractions of the blood of neurosyphilitic patients following treatment. Rosen, Krasnow, and Notkin<sup>1</sup> have found a distinct increase in the amount of lecithin in the blood of syphilitic patients after treatment. Bischoff, Maxwell, and Hill<sup>2</sup> and Daly and Knudson<sup>3</sup> have demonstrated that there is a shift in the phosphorus equilibrium during hyperthermia.

### PLAN OF EXPERIMENT

The results of the work cited above would indicate that the treatment of paresis with hyperpyrexia might have a definite influence upon the phosphorus partition of the blood. This problem was approached by the following procedure: Fifteen patients diagnosed as typically paretic were chosen for this study; nine were treated by the electric blanket method<sup>4</sup> and six with inoculated tertian malaria. A phosphorus partition, involving inorganic, total acid-soluble, organic acid-soluble, lipin, and total phosphorus, was determined upon the whole blood of each patient before and after the treatment series. Those treated by the electric blanket method each received twelve treatments, and those who were given malaria were each allowed to have five paroxysms.

\*From the Illinois State Psychopathic Institute.  
Received for publication, October 9, 1933.

The blood for analysis was taken in the morning after a fifteen-hour fast, and the patients, while undergoing the series of treatments, were kept under carefully controlled hospital conditions.

The methods of analysis used in this study were those recommended by Walker and Huntsinger.<sup>5</sup> Each determination was done in duplicate and checked independently by two workers. Mean values were used when duplicate determinations did not agree.

## RESULTS

The data incorporated in Table I give the findings of the various phosphorus partitions before and after treatment. The accuracy of the analytic methods employed is demonstrated by the close agreement between the total phosphorus by direct analysis and the sum of the acid-soluble and lipin fractions. This table also gives the status of each patient following treatment.

Table II gives the amount of lecithin per 100 ml. of whole blood for each patient before and after treatment. These figures were obtained by multiplying

TABLE II  
LECITHIN CONTENT OF WHOLE BLOOD IN PARETIC PATIENTS BEFORE AND AFTER TREATMENT  
WITH HYPERPYREXIA

the lipin phosphorus by 25, as lecithin contains 4 per cent phosphorus. This gives recognition only to the lecithin content of this fraction, but this has been found accurate enough for comparative purposes. The status of each patient following treatment is also included in this table.

## DISCUSSION

Bischoff et al.<sup>2</sup> have found that during hyperthermia part of the inorganic phosphorus in the blood is converted into acid-soluble organic phosphorus with an alkaline shift in the blood  $P_H$ . They have suggested that this is an in-vivo duplication of the in-vitro conversion of inorganic to organic phosphorus in blood as first demonstrated by Lawaczek.<sup>6</sup>

Daly and Knudson<sup>3</sup> in their experiment in hyperthermia were unable to confirm the observation of Bischoff and his coworkers that the alkalosis occurring during hyperthermia was accompanied by an increase in the acid-soluble organic phosphorus and a decrease in the inorganic fraction. They found that there was a lowering of both inorganic and acid-soluble organic phosphorus of whole blood and plasma during alkalosis.

It was also shown by Rosen et al.<sup>1</sup> that patients with neurosyphilis, who improve following treatment, show an increase in the lecithin content of their blood.

Referring to Table I and excluding patients 4 and 5, who did not improve following treatment, a lowering of the inorganic phosphorus content is shown in eight of the thirteen improved cases. Again nine of these thirteen patients had a loss of organic acid-soluble phosphorus. This table also shows that all of the thirteen improved cases had an increase in the amount of the lipin phosphorus fraction.

The above facts are not in perfect agreement with the findings of either Bischoff or Daly and Knudson. This perhaps can be explained by the fact that their analyses were done during the period of hyperthermia while samples analyzed in this problem were taken at the normal body temperature before and after the treatment series. However, the results of the majority of our analyses agreed with the findings of Daly.

There is evidence that the synthesis of phosphatides from inorganic phosphates can take place in the body.<sup>7</sup> Animals have been shown to develop normally when their only source of phosphorus was in the inorganic form, and to be capable of forming both organic phosphorus for their bodies and lecithin for their eggs. It is significant to note, therefore, that in nine of the thirteen improved cases there was an increase in the lipin fraction accompanied by a lowering of both the total acid-soluble and organic acid-soluble phosphorus. This might be used as evidence that part of the acid-soluble fraction had been converted into lipin phosphorus as a result of the hyperpyrexia.

Regarding the total determined phosphorus in Table I, it will be noticed that there were no significant changes in the amount following treatment in the thirteen improved cases. It increased in five, decreased in seven and remained constant in one. This would suggest that the increase in the lipin phosphorus was not caused by an increase in the total amount of phosphorus in the blood, but represented only a shift from one fraction to another.

The only significant change observed in the unimproved Cases 4 and 5 was that there was a decrease in the amount of lipin phosphorus after treatment. This may prove to be indicative, but two cases can hardly be considered as sufficient evidence to arrive at any definite conclusion.

Table II shows that there was an increase in the lecithin content of the blood of the improved cases. This agrees with the findings of Rosen et al.<sup>1</sup>

#### CONCLUSIONS

1. Parietic patients who improved following treatment by hyperpyrexia showed an increase in the lecithin content of their blood.
2. There seemed to be a conversion of acid-soluble phosphorus to lipin phosphorus following treatment by hyperpyrexia in those cases which improved.
3. The increase in the amount of lipin phosphorus in the blood of improved patients following hyperpyrexia was not accompanied by a corresponding increase in the total determined phosphorus, and would seem to be a partitional change.

## SPINAL FLUID SUGAR DETERMINATIONS IN EXPERIMENTAL HYPOGLYCEMIA OF DOGS\*

---

REUBEN DAVIS, M.D., AND HERMAN BROWN, B.Sc., PHILADELPHIA, PA.

---

RECENTLY one of us (R. D.) had occasion to treat an unusual case of severe insulin shock. The patient, a man aged thirty-one years, was a known diabetic patient and, while under the influence of alcohol, took 30 units of insulin before the evening meal, which was twice his prescribed dose. He promptly vomited and members of his family thinking he was going into a diabetic coma administered two more 30-unit doses of insulin. The patient became more stuporous during the night and was sent to the hospital in the morning.

On admission his blood sugar was 21 mg. per 100 c.c. A total of 100 gm. of glucose was given intravenously, but the patient did not regain consciousness though the blood sugar was then 164 mg. per 100 c.c. Intravenous injections of glucose were continued but the patient died without regaining consciousness. The blood sugar after death was 176 mg. per 100 c.c., but the spinal fluid sugar was only 25 mg. per 100 c.c.

It is difficult to evaluate the rôle played by alcohol in this case but the discrepancy between blood and spinal fluid sugar results made it desirable that a study be made of the blood and spinal fluid sugar in experimental hypoglycemia in the hope that the poor response of such patients to large amounts of injected glucose might be explained.

### EXPERIMENTAL

Normal dogs of both sexes and various weights were used. Insulin was administered after a twenty-four-hour fasting period. Blood was taken from the jugular vein and spinal fluid obtained by cisternal puncture without anesthesia. The specimens were preserved with sodium fluoride and the glucose determinations made by the method of Folin and Wu.<sup>1</sup>

Table I lists the blood and spinal fluid sugar findings of five normal dogs. It is generally agreed that in a state of health the blood and spinal fluid sugar are in a fairly definite relationship to each other. However, we are unaware of

\*From the Department of Medicine of Temple University and the Research Institute of Cutaneous Medicine of Philadelphia.

Received for publication, October 11, 1933.

any simultaneous determinations made on the experimental animal. Kasahara and Uetani<sup>2</sup> though giving figures for spinal fluid sugar following insulin injections did not report simultaneous blood sugar values, and the relationship of the two values were only assumed. In humans this ratio is approximately 4:3 which corresponds closely to what we have found in dogs.

In the production of hypoglycemia in dogs Drabkin and Shilkret<sup>3</sup> used 20 units of insulin per kilogram. In our work we used smaller doses, not considering it desirable to produce the severe hypoglycemia that is obtained with such large doses. Our dosage ranges were between 2 and 10 units per kilogram with one exception. Dog No. 8 received 15.8 units per kilogram. The criteria of shock were listlessness, apathy, unsteady gait, vomiting, and loss of control of bowels and bladder.

It will be noted from Table II that in no case did the spinal fluid fail to show a decided decrease in sugar following insulin administration. The two dogs receiving insulin intraspinally showed a somewhat greater proportional fall in spinal fluid sugar per unit of insulin but part of this excessive decrease might be accounted for by simple dilution of spinal fluid by the insulin. The blood and spinal fluid sugar relationship is definitely disturbed; in only one animal was the normal ratio maintained. It is also noteworthy that in very severe hypoglycemia (dog No. 8) the effect on the spinal fluid sugar is proportionally so much greater as to cause this ratio to approach two. Insulin is active intraspinally; the blood sugar findings, however, indicate that it is no more efficacious than when administered subcutaneously.

The influence of intraspinal glucose administration upon insulin hypoglycemia is illustrated in Table III.

After shock had been attained in the six dogs, varying amounts of glucose solution were injected intraspinally. Following each injection, the blood sugar, as well as the spinal fluid sugar, was determined in order to see if there was a rise in the blood value coincident with any improvement noted.

Mater<sup>4</sup> has reported a constant rise in the blood sugar following the injection of air and Ringer's solution into the subarachnoid space, amounting to 200 mg. per cent in some cases. Such a rise, however, could be suppressed by the preliminary use of insulin. Our results confirm these observations, the blood sugar rising but little following intraspinal glucose injections in the insulin-treated dogs.

In all our cases of intraspinal glucose injections the improvement noted was transient and difficult to evaluate. To eliminate the possible effect on the clinical improvement of the stimulation caused by performing a cisternal puncture, one animal was injected with normal salt solution. This injection was without effect (dog No. 6, Table III). Wagging the tail and loss of apathy were taken as criteria of improvement. Such changes were but temporary, and in order to save the animal at the end of the experiment it was necessary to administer glucose intravenously.

Dog No. 5 was given a very large dose of insulin and severe shock with convulsions was produced. Repeated intraspinal injections of glucose solution failed to ameliorate the symptoms despite the fact that the spinal fluid sugar reached a level more than twice normal.

During the course of this work it was interesting to note the rapidity with which glucose, injected intravenously, penetrated into the spinal fluid.

Thus following the injection of 25 c.c. of 50 per cent glucose in seven minutes the spinal fluid sugar of dog No. 5 rose from a hypoglycemic value of 28 to 78 mg. per 100 c.c. Dog No. 6 showed a similar rise. However, such

rapid penetration does not occur in nonhypoglycemic humans as was shown in the studies of Levinson.<sup>5</sup> Such rapid penetration of the meninges is probably not equaled by any other physiologic constituent.

## DISCUSSION

Cases of diabetes mellitus that present unmistakable symptoms of insulin shock when the blood sugar is at a relatively high level are not unusual. Such

TABLE IV

IN HYPOLYCEMIC DOGS

| DOG NO. | BLOOD SUGAR | SPINAL FLUID SUGAR |                                            |
|---------|-------------|--------------------|--------------------------------------------|
|         |             | BEFORE GLUCOSE     | AFTER 25 C.C. 50% GLUCOSE<br>INTRAVENOUSLY |
| 5       | 61          | 32                 | 78 (7 min. later)                          |
| 6       | 34          | 28                 | 73 (10 min. later)                         |

cases usually respond to carbohydrate ingestion, despite the fact that the blood sugar values may range between 150 and 200 mg. per 100 c.c., or more. John<sup>6</sup> has attempted to explain such cases of shock on the basis of a decreased permeability of the corpuscles in the diabetic patient. Other observers<sup>7, 8</sup> on the other hand have found an increased permeability of these cells. Our own work throws no additional light on this phase of the subject. It is apparent that meningeal permeability is quite high in the ordinary case of insulin hypoglycemia, and patients in such cases recover quite promptly following intravenous glucose injections; but it is conceivable that in such cases as the one reported here meningeal permeability may be markedly decreased. Under such circumstances insulin shock might persist even though, by intravenous glucose injections, high blood sugar values are obtained. Decreased meningeal permeability could be ascertained by spinal fluid sugar determinations and, if low values are found despite high blood sugar figures, intraspinal injections of glucose might be resorted to.

#### CONCLUSIONS

1. Insulin, in the normal animal, has a uniform action in lowering the spinal fluid sugar. Such decreases are often of greater proportion than the blood sugar reductions.

2. There is only a temporary improvement following intraspinal glucose injections in hypoglycemic dogs. A sustained high spinal fluid sugar without a commensurate high blood sugar will not preserve the life of the animal.

3. Glucose injected intravenously during hypoglycemia enters the spinal fluid very rapidly in the experimental animal.

4. Intraspinal glucose injections should be resorted to in the hypoglycemic diabetic who does not respond to intravenous glucose injections.

# THE BLOOD LIPASE IN PATIENTS WITH PEPTIC ULCER\*

## ITS RELATION TO HEPATIC AND PANCREATIC DISEASE

FLOYD H. JERGESEN, M.S., M.B., AND J. P. SIMONDS, PH.D., M.D.,  
CHICAGO, ILL.

CHERRY and Crandall<sup>2</sup> found an enzyme capable of splitting olive oil in the blood of dogs after experimental damage to the pancreas. They<sup>2</sup> found the same lipolytic enzyme in 80 per cent of the cases of liver disease studied. In their opinion, the only conditions in which this enzyme appears in increased amount in the blood, both in the dog and in man, are pathologic changes in the liver and pancreas.

Occasional reference is made in the literature to lesions and dysfunction of the liver and pancreas associated with peptic ulcer. Thus, Gandy,<sup>3, 10</sup> in 1899 and again in 1920, mentioned lesions of the liver found in cases of peptic ulcer. Pathologic changes in the liver and kidneys have been suggested by LeNoir, Richet, and Jacquelin<sup>16</sup> as the cause of death of five patients following surgical procedures for peptic ulcer. Since the hepatic alterations could not be demonstrated by clinical methods they<sup>18</sup> employed laboratory tests. Unfortunately, some of the liver function tests they used were of questionable value, namely, provoked glycosuria and digestion hemoclasia. Because in a considerable percentage of cases of gastric ulcer the fasting blood sugar and the glycemic coefficient were greater than normal, LeNoir, de Fossey and Richet<sup>15</sup> concluded that the changes were due to disturbed hepatic function. That hepatorenal insufficiency may be found in cases of carcinoma of the stomach but is more frequent and more marked in peptic ulcer is the opinion of LeNoir, Richet and Jacquelin.<sup>17</sup> Vilardell and Lloret<sup>26</sup> demonstrated by means of biopsy definite microscopic lesions of the liver in patients with peptic ulcer.

Cases of clinically manifest jaundice associated with gastric and duodenal ulcer have been reported by Tiprez and Dumont,<sup>24, 25</sup> and the relation of jaundice to disease of the liver and biliary tract has been discussed by Surmont,<sup>23</sup> Bickel,<sup>1</sup> and Zoepffel.<sup>27</sup> Masked jaundice associated with peptic ulcer and demonstrated by means of the Van den Bergh reaction has been investigated by Hadlich,<sup>11</sup> and by Kalk and Siebert.<sup>14</sup> Cholecystitis and cholelithiasis have been found accompanying ulcer of the duodenum (McVicar and Weir,<sup>20</sup> Judd,<sup>13</sup> Bruce,<sup>2</sup> Mix,<sup>22</sup> MacLaren and Oertling<sup>19</sup>).

Meyer<sup>21</sup> reported two cases of renal glycosuria with ulcer of the duodenum and thought it might be due to an associated infection of the pancreas. Jankelson and Rudy<sup>12</sup> stated that a nondiabetic glycosuria in cases of peptic ulcer was suggestive of an adjacent chronic pancreatitis. The relationship between lesions of the pancreas and ulcers of the duodenum and stomach has been dis-

\*From the Department of Pathology, Northwestern University Medical School.

cussed by Ehrström and Nylander.<sup>7</sup> Dysfunction of the pancreas has been investigated by means of spontaneous and provoked glycosuria, hyperglycemia, and the diastase content of the blood and urine by Galli, Pecco and Polacco.<sup>8</sup> These authors considered pancreatic dysfunction to have been present in 32 per cent of the cases studied.

In order to apply a more reliable test to the problem of the possible association of disturbance of the functions of the liver and pancreas with ulcer of the stomach and duodenum, we have employed the method described by Cherry and Crandall<sup>3</sup> and have studied the lipase content of the blood of fifty patients with peptic ulcer and of twenty-five control patients.

#### METHOD

In each of two test tubes 1 c.c. of blood serum was added to 3 c.c. of distilled water. One tube was inactivated at 90° C. for five minutes. This inactivated tube was used as the control. To each tube were added 2 c.c. of a 50 per cent emulsion of olive oil and 0.5 c.c. N/3 sodium phosphate buffer adjusted to  $P_H$  7.0. The contents of the tubes were thoroughly mixed and incubated at 40° C. for 24 hours. At the end of that time they were titrated with N/20 sodium hydroxide, using three drops of 1 per cent alcoholic solution of phenolphthalein as an indicator. The results have been expressed in cubic centimeters of N/20 alkali necessary to neutralize the fatty acids set free in 1 c.c. of olive oil.

In 60 determinations of inactivated serum it was found that the limits of variation were not more than 0.2 c.c. of N/20 NaOH. Since this corresponds with the results of Cherry and Crandall we have considered 0.2 c.c. as the limit of experimental error, and any reading of 0.3 c.c. or greater has been recorded as positive.

#### DISCUSSION

The results of the blood lipase determinations of fifty patients with peptic ulcer are found in Table I. In all cases except one roentgenologic evidences of peptic ulcer were present. The patient in case 8 was proved to have a duodenal ulcer at operation. A lipase titer of 0.3 c.c. or greater N/20 sodium hydroxide was found to be present in 38 cases, or 76 per cent. No relation between the lipase content of the blood and the age or sex of the patient could be demonstrated.

In most cases the clinical history was the only source of information available to us by which an estimate could be made as to the approximate duration of the ulcer. An appreciation of the questionable accuracy of this method was fully realized since it is well known that many cases of peptic ulcer come to necropsy although no definite symptoms of ulcer were present during life. However, in a few cases roentgenologic evidences and previous surgical operations gave a more accurate criterion as to duration. In our studies no connection could be found between the amount of blood lipase, as indicated by the alkali titer, and the approximate duration of the ulcer.

Only four cases of gastric ulcer were studied. The blood lipase titer of these patients was 0.5, 0.6, 0.6, and 0.4 c.c. N/20 sodium hydroxide. It seems probable, therefore, that the presence of an ulcer in either the stomach or duodenum may be associated with an increase of the blood lipase titer.

The effect of alimentary lipemia by increasing the total amount of fat for the enzyme to act upon, thus liberating more fatty acids, was considered. In the control cases no alteration in the titrations due to this factor was noted. The blood was taken from the ulcer patients before or after meals or after 12

All were males except 21, 34, 49, and 50.

The Wassermann reaction was positive in 7 and 13 and negative or undetermined in the remainder.

Nine patients had some type of surgical procedure on the stomach, usually a gastroenterostomy.

Various types of therapy were used: alkalis, citrosalvan, mucin, or chondroitin.

hours of fasting. Alimentary lipemia either caused no change in the lipase titer, or it was so small as to be negligible.

Crandall and Cherry<sup>4</sup> found in 146 control patients that six gave a titration of 0.3 c.c. or more N/20 NaOH. In order to check our technic twenty-five unselected patients were studied. After making the determinations, none of the patients were found to have symptoms referable to hepatic disease or peptic ulcer. One patient was said to have "some pancreatic involvement." Three patients in this group gave positive results. The lipase titer and diagnosis in these cases were as follows: 0.5 c.c. N/20 sodium hydroxide, hypertension, nephrosclerosis and arteriosclerosis; 0.5 c.c. N/20 sodium hydroxide, possible kinking of the right ureter; 1.2 c.c. N/20 sodium hydroxide, diabetes mellitus, pyelitis, cystitis, and nephritis.

Evidence has recently been presented by Ivy, Schrager, and Morgan<sup>28</sup> that disturbance of hepatic function may be an etiologic factor in the occurrence of gastric and duodenal ulcer. The experiments here reported throw no light on this problem. Although we found positive evidence of disturbance of the

function of the liver or pancreas or of both together in 76 per cent of the cases of gastric and duodenal ulcer studied by a new and apparently reliable test, the lesions underlying these functional disturbances might just as well have been secondary to the ulcer as a primary and etiologic factor in its production.

### CONCLUSIONS

1. An enzyme capable of splitting olive oil was found to be present in the blood of 38 (76 per cent) out of 50 patients with peptic ulcer.
2. The amount of this enzyme present, indicated by its alkali titer, had no relation to the probable duration of the ulcer or to the age or sex of the patient.
3. It is suggested that this lipolytic enzyme in the blood is due to associated dysfunction of the pancreas or liver or both.

4. This test may prove valuable in preoperative determination of the presence of one factor of the surgical risk, namely, pathologic changes in the structure or function of the liver and pancreas, in patients with peptic ulcer.

We wish to thank Dr. Clarence E. Brown of St. Luke's Hospital and Dr. Harry Singer of the Cook County Hospital for the privilege of using their clinical cases for this study.

## CARCINOMA OF THE PANCREAS\*

FORD K. HICK, M.D., AND HAROLD M. MORTIMER, M.D., CHICAGO, ILL.

IN AN attempt to determine the frequency and symptomatology of carcinoma of the pancreas we have reviewed 50 cases proved at autopsy, seen during the period from January 1, 1925, to January 1, 1933. The records are from the Cook County Hospital, and a smaller number are from the Research and Educational Hospital. The majority of the autopsies were performed by Dr. R. H. Jaffé, pathologist at the Cook County Hospital. Clinically diagnosed cases, even those confirmed by laparotomy but not proved by necropsy, are omitted because of the great difficulties in diagnosis. Metastatic carcinoma of the pancreas is not mentioned.

Knowledge of carcinoma of the pancreas certainly goes back to 1857, when the elder Da Costa<sup>1</sup> wrote of it. Mondiere<sup>2</sup> in 1836 is quoted as having written about it. Ancelet<sup>3</sup> in 1864 includes mention of it in his monograph. However Bard and Pic<sup>4</sup> in 1888 first described the clinical picture accepted as classical of carcinoma of the head of the gland. Knowledge of this last work has gradually pervaded the whole of medical literature. French writers since that time have accorded carcinoma of the pancreas a relatively important place in their medical literature.

The 50 cases occurring in 7,932 autopsies constitutes 0.63 per cent of all necropsies. In this group there were 942 malignancies of all sorts. Primary carcinoma of the pancreas made up 5.3 per cent of all malignancies. Carcinoma of the stomach was seen 211 times, 22.3 per cent of all malignancies. The ratio between the number of carcinomas of the stomach to those of the pancreas is roughly 4 to 1. Kolb,<sup>5</sup> in 1907, found 54 carcinomas of the pancreas in men among 8,777 deaths due to malignancy, and 50 in 11,266 similar cases in women. There was in his statistics a ratio of 87 carcinomas of the stomach to one carcinoma of the pancreas in male. Our figures are more in agreement

\*From the Department of Pathology, Cook County Hospital, R. H. Jaffé, Director, and the Department of Medicine, University of Illinois.  
Received for publication, October 21, 1933.

with figures from the Massachusetts General Hospital.<sup>6</sup> Here in 700 necropsies, 14 carcinomas of the pancreas were found while there were only 17 cancers of the stomach. Ewing<sup>7</sup> from large statistics states that carcinoma of the pancreas constitutes from 1 to 2 per cent of all malignancies. Of Kauffman's<sup>8</sup> cases of malignancy examined postmortem, 1.76 per cent were in the pancreas.

In our series of cases males were much in the majority, as 41 were in men and only 9 in women. Correcting for the preponderance of postmortems on men, the authors find the incidence would be 41 men to 18 women. In most series described in the literature this ratio holds.

|                       | TOTAL CASES | MEN | WOMEN | HEAD | BODY AND<br>TAIL | ENTIRE<br>GLAND |
|-----------------------|-------------|-----|-------|------|------------------|-----------------|
| Mirallie <sup>9</sup> | 104         | 69  | 35    | 39   | 7                | 19              |
| Speed <sup>10</sup>   | 52          | 36  | 16    |      |                  |                 |
| Fuchter <sup>11</sup> | 31          | 22  | 9     |      |                  |                 |
| Kiefer <sup>12</sup>  | 33          | 18  | 15    | 24   | 5                | 4               |
| Wallau <sup>13</sup>  | 330         | 196 | 134   | 169  | 46               | 125             |
| Ewing                 | 354         |     |       | 156  | 40               | 158             |
| Oser <sup>14</sup>    | 26          |     |       | 20   | 5                | 1               |

Though a fair share (38.4 per cent) of the autopsies are on colored people, only five of our patients were negroes.

Of the 50 in this series, in only 22 was the growth limited to the head of the gland. In 23 cases the neoplasm arose in either the body or tail. In only four cases did the neoplasm occupy the entire pancreas. One was from an aberrant pancreas in the wall of the duodenum. The high proportion of carcinoma of the body and tail, namely 46 per cent, is in striking contrast to the figures of others.

All cases in which the carcinoma arose in the common duct have been excluded. As pointed out by Shapiro and Lifvendahl,<sup>15</sup> who worked with practically the same material, neoplasms of the biliary passages are often mistaken for carcinoma of the head of the pancreas even at laparotomy. They showed that biliary duct carcinoma occurred much more frequently than carcinoma of the head of the pancreas.

#### ANATOMIC FINDINGS

Grossly the tumors of the pancreas ranged from 3 cm. in greatest diameter to as large as 12 cm. The consistency ranged from firmness to stony hardness. Characteristically their growth was invasive into the neighboring organs and the remainder of the pancreas. In no case was there any semblance of a capsule. White streaks often outlined the lymphatics through which the tumor had extended.

Microscopically it was found that 27 of the tumors were the adenocarcinoma form; 16 were scirrhus; two, medullary; two, alveolar; and one, simplex. Two are unclassified types of highly undifferentiated carcinoma. The microscopic diagnosis bore no relation to the duration of the disease or the extent of metastases. The three cases in which there were no metastases were all scirrhus.

The pancreatic ducts were often obstructed and hence distended in the distal part of the gland. The circumference of the dilated duct commonly reached 30 mm. The gallbladder was found dilated in all but two of the 19 cases of carcinoma of the head of the pancreas with jaundice, and one of these patients had had a cholecystectomy years before. Courvoisier's rule holds, therefore, in roughly 95 per cent of these cases. However in only 6 patients were the clinicians able to palpate the gallbladder.

Metastases of these tumors are very important since they dominate the clinical and pathologic picture in many patients. In only three patients were there no metastases; all three tumors were in the head of the gland and were of the scirrhus type. The lymph nodes in the upper abdomen and the liver were most regularly affected, each showing metastases in 68 per cent of the cases. Carcinomatosis peritonei was found in 22 cases, though only 9 had an ascites that was demonstrable clinically. Lymphatic spread to the mediastinal glands and the pleura was quite frequent. Even a carcinomatous lymphangitis of the right upper lobe was found in one case. Liver metastases, contrary to being small as described by Bard and Pic are of fair size averaging from 3 to 7 cm. and reaching 15 cm. in diameter.

Involvement of the stomach by direct extension of the neoplasm occurred six times, all in carcinomas of the body or tail of the gland. The duodenum was invaded seven times. This anatomic lesion will explain the common finding of blood in the stools, as well as the frequent false results of roentgenologic examination of the stomach.

Bizarre metastases are quite frequent and often occur early in the course of this disease. One carcinoma had invaded both ureters from retroperitoneal metastases and given rise to hematuria. Another had extensively riddled the submucosa of the entire small bowel. One invaded the transverse colon causing an obstruction. A fourth had caused a kink at the splenic flexure by fixing its supporting mesocolon with carcinomatous infiltration. Only one had metastases at the umbilicus. Only one had invaded the bones, the invasion being the result of direct extension from metastases in the mediastinal lymph nodes.

In contrast to the lymphatic spread which was so common, distant hematogenous metastases<sup>16</sup> were found in only two cases. Both showed lymphatic spread from a primary tumor of the body of the gland as well. The first such case had an extensive lymphatic spread to all the viscera of both chest and abdomen, and in addition had multiple intracutaneous nodules of carcinoma over the face, neck, and shoulders. Another case showed involvement of the retroperitoneal lymph nodes and also had an isolated metastasis in the myocardium.

#### PATHOGENESIS

There is no apparent connection between carcinoma of the pancreas and regeneration. Cirrhosis of the liver with associated cirrhosis of the pancreas is rarely followed by carcinoma of the pancreas. Only three such cases were found in the literature.<sup>17</sup> In these cases proliferation of the duct epithelium may be a precancerous lesion. In cases of chronic obstruction to the pan-

creatic ducts from any cause, the acini may atrophy while the duct system often proliferates producing buds of tissue like the islands of Langerhans. One of this series showed a moderate degree of this process. In three cases, multiple small congenital cysts were found in the pancreas, whose occurrence might suggest the theory of carcinoma arising from misplaced embryonic tissue, the cell rests of Cohnheim or the hamartomas of Albrecht. Interstitial pancreatitis as a precursor to carcinoma was not found here. Gallstones were an associated observation in only 6 of the 50 cases.

T. Cherry<sup>18</sup> of Melbourne produced carcinoma of the pancreas in mice, experimentally, by inducing chronic inflammation of the area by the injection of tubercle bacilli to which mice are resistant. He showed carcinoma arising from the ducts in these animals, with intermediate stages present.

Among these 7,932 necropsies, there were found two small adenomas of the islands of Langerhans. One was seen in a pancreas in which a carcinoma had arisen from the ducts. The other adenoma was purely an incidental finding at autopsy. Neither of these patients presented any symptoms of hyperinsulinism.

#### CLINICAL RECORDS

Since three patients entered the hospital moribund, and no adequate history could be obtained from another patient, the study is limited to 46 clinical records. Of these cases the duration of the process judged from the onset of the first symptom that could be ascribed to the lesion in question, varied from two weeks to three years for an average of 6.9 months. Only five said their trouble was of more than one year's standing.

Pain was the first symptom noted in 23 cases. Weight loss was noted first in 6, jaundice in 6, anorexia in 7, abdominal distension in 3, and edema of the legs in one. Pain and weight loss were the most constant symptoms occurring in 43 cases, or 93.4 per cent; next was anorexia in 30 cases or 65 per cent; then jaundice in 23 cases or 50 per cent; constipation in 17, or 36.9 per cent; vomiting in 16, or 34.8 per cent; and nausea alone in ten others. Diabetes was present in eight, or 17.4 per cent. Polyphagia was present in three cases. Diarrhea was a complaint of only one patient. Kiefer in his series of 33 found cachexia, including loss of weight to be the most common symptom, jaundice second, and pain third. Speed in his group also found these three symptoms to be the most common in the order named.

Pain was undoubtedly the most constant symptom. Kiefer reports it as a symptom in 21 of 33 patients. Speed has it recorded in 61 per cent of 52 cases, while Mirallie writes of it as an important symptom in 56 of 113 patients. The pain was most frequently epigastric in location, being there in roughly three-fourths of all the patients. It varied from a soreness to a most excruciating type of paroxysm requiring narcotics for relief. It occasionally radiated around the costal margins and in a few instances even up into the chest. In the case with ureteral involvement, pain radiated down to the groins. Little relation was noted between the pain and the time or type of food-taking; however, it was frequently produced at the onset by taking very large meals and fatty foods. In only two instances it was partially relieved by alkalis or by

vomiting. These two patients got relief with Sippy ulcer management for a period of two weeks, after which that was not effective.

Pain in the back occurred in association with epigastric pain in 15 cases while it was limited to the back in 2 patients. This symptom, pain in the back, has been noted in the literature particularly by Chauffard,<sup>19</sup> who in 1908 drew attention to its presence in carcinoma of the body of the pancreas. The pain is characteristically located in the lower dorsal and upper lumbar regions of the back, and is most often to the left of the midline. It is severe and relieved in many instances only by the *upright position of the body* as by sitting up, walking with the body bent forward at the hips, or lying curled up on the right side. Lying on the back seemed to aggravate the pain, and so quite often the patients described the pain as being worse at night or said that it first bothered them during the night. Of the 15 cases in which the pain occurred in the back, the tumor was found in 9 to involve the body or tail of the gland; while 4 were primarily in the head, and two occupied the entire organ. Eleven of the 15 patients with pain in the back showed at autopsy a carcinomatous involvement of the body of the pancreas, which suggests that this symptom may be of diagnostic significance in doubtful cases. As to the way the pain is produced, obstruction of the pancreatic duct with its subsequent distension is one theory; just as dilatation of the biliary ducts is thought to cause pain. Invasion of the celiac plexus by the newgrowth is the most commonly accepted explanation. Many cancers which have retroperitoneal metastases, as carcinoma of the stomach, liver, or lung, produce pain in the back as a distressing symptom, even in the absence of metastases to the spine. We have not observed any postural relief of the pain in any of these other tumors.

Anorexia was a major complaint of 21 cases being associated slightly more often with carcinoma of the head (56 per cent) than with carcinoma of the body of the gland (47.5 per cent). Nausea and vomiting usually followed in sequence. The loss of appetite bore no relation to the presence of icterus or to duodenal obstruction. In fact of 13 showing direct invasion of the duodenum or stomach, only 5 patients had anorexia among their chief entering complaints.

Hematemesis did not occur in any of this series even in those with malignant ulcers in the stomach although 8 of the 21 cases having gastric analyses showed occult blood in the stomach content.

Jaundice, so strikingly a part of the picture of carcinoma of the pancreas since Bard and Pic wrote of it, was by no means constantly present. It occurs here in 23 of the 50 cases. It was the initial symptom in only 6 cases. It was absent in 3 of the 22 cases having carcinoma of the head of the pancreas. Since the jaundice is due to the compression of the common duct by tumor tissue, no jaundice follows when the tumor spreads in such fashion as to miss the common duct. Jaundice was present in 3 of the 4 cases of carcinoma of the entire gland, and appeared once as a result of compression of the hepatic ducts by a metastasis from a cancer in the body of the gland. Once the jaundice appeared it did not recede, save in one woman who was icteric for 4 months and recovered only to have a recurrence of the icterus 6 months later, this time with weight loss and a progressive downhill course. The icterus indices ranged up to 250.

Jaundice and pain appeared often together for of 19 cases with obstruction of the common duct due to malignancy, there was severe pain in 17 instances. Though usually in the right upper quadrant the pain varied somewhat. E.N. had his pain in the back on the left side all the time. The pain in J.B. was of ulcer type and responded to Sippy management for a time. L.S. had only a slight epigastric distress though there was a carcinoma completely obstructing the common duct and causing a very large gallbladder. J.C. alone of this icteric group was entirely free from pain. In general when present with jaundice in cancer of the head of the pancreas, the pain was usually moderately severe, aching in character, and spontaneously remittent for short periods. It bore no definite relation to postural relief save in one case. At no time had there been colics requiring morphine.

Weight loss ranged from 10 to 80 pounds, averaging 37 pounds. It was the first symptom in 7 patients and had taken place in from two weeks to one year. Kiefer described an average weight loss of 28 pounds and stressed the speed with which it took place.

Diabetes was present in eight cases, or 17.8 per cent. This is a much higher proportion of diabetes than others have given. Joslin<sup>20</sup> says the association is very unusual and quotes from Kiefer. Three of the patients had known of their diabetes before they entered the hospital. One of the latter first knew of her glycosuria when she consulted a physician because of epigastric pain and pruritus vulva. The blood sugar values on these 8 patients ranged from 166 to 250 mg. per cent. In 2 of these 8 cases the entire gland was affected while in 3 the tumor was in the body, and the remaining three were primarily in the head of the pancreas. In the latter three one had an atrophy of the distal portion of the gland, and another showed multiple cysts occupying the body and tail of the gland with a virtual destruction of the parenchyma.

Polyphagia was present in three cases. Two of these had diabetes to which the symptom may be ascribed. The remaining case showed no other manifestation of a suspected hypoglycemia and did not have an adenoma of the island tissue at necropsy, but instead a scirrhous carcinoma. Not a single case presented the symptom complex described by Wilder et al.<sup>21</sup>

Diarrhea was present in only 1 of the 46 patients. Constipation was a complaint that had been present in 17 patients for variable periods up to many years. Without a single case of fatty stools recorded this lone instance of diarrhea would indicate that loose fatty stools with jaundice occur less frequently than is supposed. The frequency of constipation only emphasizes the rarity of diarrhea.

#### PHYSICAL FINDINGS

On examination of the abdomen a tumor mass was palpable in 35 cases. In 25 these masses were in the right upper quadrant and had been called metastatic tumors of the liver. In 7 instances the mass was limited to the epigastrium or spread to the left hypochondrium. In 5 cases both upper quadrants showed masses. All of the masses were hard, only a few nodular. As a rule the masses in the epigastrium were fixed, but in at least two instances in

which the carcinoma protruded anteriorly from the body of the gland, a movement of 3 cm. or more with each respiration was noted.

Ascites was found in 8 cases on clinical examination. Each was due to a carcinomatosis peritonei. In one instance the carcinoma nodules could be palpated through the abdominal wall. Rectal examination in three cases revealed hard lumps in the culdesac which proved to be drop metastases. Two had been thought to be a primary carcinoma of the rectum.

Fever was present during the hospital stay of 10 patients, or 21 per cent. The temperatures ranged from 97° to 102° F. Bard and Pic thought these cases all had subnormal temperature.

#### ROENTGEN FINDINGS

The x-ray examination was found to be of little help in the diagnosis in most instances. On the contrary misleading information was not infrequently obtained. Of 6 cases in which fluoroscopic examinations revealed stomach defects, 4 were infiltrations of the greater curvature by the pancreatic newgrowth. Two more were reported as pyloric obstruction. In a patient having metastases to the mediastinal glands the roentgenogram was that of a carcinoma of the esophagus. A single case showed what was taken to be an extragastric mass with displacement of the stomach. One that had invaded the transverse colon gave the findings of a carcinoma of the transverse colon with obstruction. Scholz and Pfeiffer<sup>22</sup> reported two cases of carcinoma of the tail of the pancreas showing a deformity of the greater curvature of the stomach due to an extragastric mass. On its presence one of their cases was accurately diagnosed. In carcinoma of the head of the gland a widening and stasis of the C-shaped duodenal loop has been described but was seen here only in the large tumor arising from an aberrant pancreas in the wall of the third portion of the duodenum. X-ray examination is chiefly helpful in these cases by ruling out pathologic processes in the stomach or duodenum.

Upon review of these clinical manifestations of carcinoma of the pancreas as shown by our series of proved cases, one is unable to point out anything absolutely characteristic. On the contrary the difficulties of an accurate presumptive diagnosis is impressed upon us. Carcinoma of the head of the gland affords perhaps the best opportunity of diagnosis with the symptoms of pain, icterus, and weight loss pointing the way. The jaundice is not, however, painless as has been stated, for pain was present in 17 of the 19 of this type of patient with icterus. Pain must be taken as a cardinal sign. We present the following as a typical case history of a patient with a carcinoma of the head of the gland.

#### CASE REPORTS

B. S., a white male, fifty-four years old, entered the Cook County Hospital July 8, 1925, and remained until September 3, 1925. He said he had been well except for a gradual loss of weight of 20 pounds in the preceding six weeks. Two weeks before entrance he had noted jaundice and marked weakness. Anorexia had appeared at the same time. During the two weeks before entrance he had taken only a little tea and cake. Pain in the right upper quadrant had been present only one week. It was dull and aching and though bothersome did not require narcotics. It did not radiate. He said that it went away if he lay quiet. He had

noticed white stools for the past two weeks. During the same time his urine was very dark. He did not have a diarrhea. Physical examination revealed a white laborer who had lost some weight but was not acutely ill. He was afebrile. The abdomen was rounded, soft and tympanitic, the liver firm and enlarged. Its edge was felt 7 cm. below the right costal arch in the nipple line. No nodules were made out in it. The rectal examination did not detect any masses. At exploration there was found ascites. The liver presented multiple metastatic nodules. There was a hard nodular mass in the region of the head of the pancreas. The gall-bladder was grossly distended. The patient died in less than three months still very deeply jaundiced, and terribly emaciated. His pain had persisted throughout the course of his illness. At autopsy a carcinoma of the head of the gland was found, with complete obstruction to the pancreatic and common bile ducts. Small metastases were present in great numbers of the liver. There were small metastases in the retroperitoneal lymph nodes. The primary tumor had invaded the second portion of the duodenum and ulcerated through the mucosa.

When the tumor involves the body and tail of the gland the diagnosis is even more uncertain but in certain cases, can be presumed. In a given case where a malignancy is suspected because of the age of the patient, loss of weight, epigastric distress, and especially pain in the upper lumbar area which responds to no simple measures save perhaps a change of posture, and with no other definite source of the tumor demonstrated, even by x-ray examination, carcinoma of the body or the tail of the pancreas is to be strongly considered. In those patients having diabetes, the attention will be focused on the pancreas. Where there has been an extension of the process to the stomach, the entire picture may exactly simulate carcinoma of the stomach.

The following case is presented as typical of carcinoma of the body of the pancreas:

I. B., a colored woman, aged sixty-one years, service of Dr. E. F. Foley, entered Cook County Hospital on June 9, 1931, and remained for seventy-five days. Her entrance complaint was of an epigastric pain, which had been present for five months, and a pain in the back, which had been present for three months. She had lost about 50 pounds in weight in the preceding six months. The epigastric pain was most intense slightly to the left of the midline. It reached its height about two hours after meals, but was present all the time. She described it as an aching or gnawing pain. Neither soda nor food brought relief. Though she was not hungry and occasionally was nauseated, she did not vomit and had not induced vomiting. The pain in the back appeared two months after the onset of the epigastric pain, which had gradually spread around either costal arch to the back. The upper lumbar and lower thoracic areas were affected, particularly on the left side. This pain was at its worst when she lay on her back. Sitting up and bending forward diminished the pain. She bent forward on walking, but could stand erect for a few minutes at a time.

Physical examination showed a colored woman who had lost much flesh, but still weighed 160 pounds. Her temperature was 99.6° F. and ranged down to 97° F. in the mornings. She was not icteric. All the physical findings were in the abdomen which was rounded and soft. There was a poorly outlined hard mass in the right upper quadrant. The kidneys and spleen were not felt. An ascites was demonstrated by the presence of shifting dullness. Rectal examination showed a hard mass about walnut size fixed in the culdesac.

Her clinical course was progressively downhill. The pain and weight loss persisted. An aversion to food developed six weeks after entrance. The ascites became so marked that she was twice tapped with removal of 2,500 c.c. and again 2,000 c.c. of a clear yellow fluid with a specific gravity of 1.020. No blood was present in this fluid. The result of the laboratory study was as follows: The urine was persistently negative for albumin, sugar, or bile. The stools were negative for blood at all times. The stomach contents showed an average free acidity of seven degrees, and a total acidity of ten. The hemoglobin was 60,

the white blood count averaged 10,300, and the red count stayed close to the entrance count of 3,700,000. The blood sugar was 85 mg. per 100 c.c.; the icterus index was 4. The x-ray examination showed nonvisualization of the gallbladder after oral administration of the dye. No anomaly was found in the stomach or duodenum. On two occasions a constant deformity with constriction of the hepatic flexure of the colon was demonstrated with barium enema.

At autopsy a carcinoma measuring  $8 \times 5 \times 4$  cm. was found in the body of the pancreas. There was an ascites due to carcinomatosis of the peritoneum. Numerous metastases were present in the liver. The hepatic flexure of the colon was bound to the undersurface of the liver by old adhesions.

#### COMMENT

It is obvious that because of the difficulties of diagnosis and the short average duration, the treatment is only palliative. The difficulties offered to surgery by the anatomic position of the pancreas and its close relation to the celiac plexus make extirpation almost hopeless, even if a diagnosis were made. As a palliative measure cholecystenterostomy has been done chiefly for relief of the icterus. A single case in this group had survived a cholecystogastrostomy. This patient was relieved of his jaundice for four months when it recurred and persisted until his death eight months postoperatively. His pain was not relieved though Speed says much relief is frequent. There is no reason to think a simple exploratory laparotomy will relieve the pain.<sup>23</sup>

#### SUMMARY

1. Primary carcinoma of the pancreas comprises 5.3 per cent of all carcinomas. It occurs about one-fourth as frequently as carcinoma of the stomach.

2. Carcinoma of the body and tail is as common as carcinoma of the head of the gland.

3. The most frequent symptoms of carcinoma of the pancreas are pain, weight loss, anorexia, jaundice, and nausea with vomiting. Diarrhea is quite rare.

4. Carcinoma of the head of the pancreas produces in three-fourths of the cases a progressively intense, moderately painful jaundice due to obstruction of the common bile duct. This cannot be differentiated from carcinoma of the biliary passages, a much more common lesion.

5. Carcinoma of the body or tail of the pancreas may be a presumptive diagnosis in the patient who is suspected of having an intraabdominal malignancy and who presents boring epigastric and upper lumbar pain partly relieved by postural changes, provided that no other primary tumor can be demonstrated. The presence of diabetes further supports this diagnosis.

6. The early occurrence of widespread metastases and the rapid progress of the disease make the treatment purely palliative.

## THE USE OF SYNTHALIN IN DIABETES MELLITUS\*

LEO K. CAMPBELL, M.D., CHICAGO, ILL.

THE purpose of this experiment was to study the action of synthalin† on the glucose metabolism in a case of diabetes mellitus.

The product used was decamethylin-diguanidin, named synthalin by Frank, Nothmann and Wagner<sup>1, 2</sup> in Breslau and first used by them in the treatment of diabetes mellitus. It was reported to have an insulin-like action when given by mouth.

### CASE REPORT

T. Q., male, aged forty-six, weighed 69 kg. This patient first developed symptoms of diabetes mellitus at the age of forty-three during an attack of pneumonia, which was followed by empyema; and at the time of the experiment he had been diabetic for three years. The diabetes had only been accurately controlled for the three weeks prior to this experiment. With a diet of carbohydrate, 76 gm.; protein, 57 gm.; fat, 183 gm.; or available glucose, "G,"† 127 gm.; cal., 2,179, and insulin, 20 units before breakfast and 10 units before the evening meal, the urine was free of sugar. He was an intelligent and well-trained diabetic patient.

### EXPERIMENT I

*Method of Study.*—The diet was made up of 800 gm. of whole milk and 800 gm. of 20 per cent cream. One third of this mixture was given between

\*From the department of medicine of Rush Medical College of the University of Chicago and the Presbyterian Hospital.

Received for publication, October 4, 1933.

†The preparation used in this experiment was obtained from C. F. Kahlbaum through Eli Lilly & Co., of Indianapolis, Indiana.

‡"G," or available glucose, was calculated by the formula, "G" = C + 0.58P + 0.10F.

8 and 10 A.M., one third between 12 noon and 2:00 P.M., and one third between 6 and 8 P.M. This diet permits of carbohydrate, 80 gm.; protein, 48 gm.; fat, 192 gm.; glucose, 127 gm.; and cal., 2,240. Four analyses during the experiment indicated that the content of C, P and F of the mixture was constant.

The complete 24-hour specimen of urine was analyzed daily for glucose by the Folin-Berglund method and polariscopy, for nitrogen by the Kjeldahl process and for creatinine by the picramic acid method. The latter was used for a check on the urinary volume. Daily fasting blood sugar determinations were made by the Folin-Wu method.

### RESULTS

When the patient was on the experimental diet, 20 units of insulin before the breakfast and 10 units before the evening meal were necessary to desugarize the urine. When 8 units were given before breakfast and none in the evening, the urinary glucose excretion was at a level that was desirable for study. This dosage was carried throughout the entire experiment. The average daily urinary glucose excretion during the fore-period from April 29 to May 3, inclusive, was 5.76 gm. During the synthalin period from May 4 to 9, inclusive, the average urinary glucose excretion was 1.56 gm. In the after-period, or May 10 to 17, inclusive, the average urinary glucose excretion was 1.90 gm. No toxic effect of the drug was noted.

In this experiment which was carried out the same as Experiment I, the level of glycosuria was within the desirable limits for experimentation without the use of insulin. The average of the daily urinary glucose excretion in the fore-period, June 2 to 10, inclusive, was 13.13 gm. and the nitrogen, 6.5 gm. During the period of the administration of synthalin, June 11 to 16, inclusive, the average daily urinary glucose excretion was 1.65 gm. and the nitrogen, 6.3 gm. In the first after-period, June 17 to 22, inclusive, the average urinary glucose excretion was 4.67 gm. and the nitrogen, 6.2 gm. In the second after-period, June 23 to 29, inclusive, the average daily urinary glucose excretion was 11.42 gm., and the nitrogen was 6.2 gm. No toxic effect of the drug was noted.

### DISCUSSION

The daily administration of 0.025 gm. of synthalin by mouth produced a well-defined reduction in the urinary glucose excretion in this diabetic patient in both experiments. The maximum effect or complete desugarization of the urine was not reached until the fourth day of administration in the first experiment and not until the sixth day in the second experiment. The failure of the level of urinary glucose excretion to return in the after-period to that of the fore-period in the first experiment was probably due to a return of natural tolerance of the patient, brought on by the period of desugarization. This was less evident in the second experiment for the glucose excretion level in the second after-period almost reached that of the fore-period.

Because of the toxic effect on the liver reported by other investigators the use of synthalin was discontinued.

## SUMMARY

The oral administration of synthalin to this diabetic patient completely desugared the urine in four to six days. The effect was sustained over a period of several days.

The author wishes to thank Dr. R. T. Woodyatt for his valuable advice and assistance during these experiments.

## BASAL METABOLISM OF OLD PEOPLE\*

YOSHIAKI KISÉ, M.D., AND TAKUMI OCHI, G.CHEM., TOKYO, JAPAN

## I. INTRODUCTION

IT IS not only for mere scientific interest but is important for practical purposes to determine the normal standard basal metabolism, since it will serve as the basic level when we discuss nutrition problems, such as food requirement, muscular work, and abnormal metabolism. In 1899, Magnus-Levy<sup>1</sup> initiated the work in this field in order to compare the metabolisms of normal and abnormal individuals.

Since then many research workers have published papers on the normal standard metabolism with improved calorimeters and technics. But the difficulty of this research work is that it requires a careful selection of subjects and technics. Especially is it true in determining the normal standard of the old age group.

In their paper Magnus-Levy and Falk presented data which showed the fact that the old age group had a lower metabolic rate than a younger group. Aub and DuBois,<sup>2</sup> Harris Benedict,<sup>3</sup> Boothby and Sandiford,<sup>4</sup> etc., discussed the basal metabolism of the old age group, and they are all in accord that metabolism is lower in older people, as long as they are in a normal condition.

However, it seems to me that their subjects were too few to discuss the fact fully, and in some papers the investigators did not include higher ages.

For the past several years we have carried out a series of experiments to determine reliable data on the normal standard metabolism for the Japanese. This paper is a result of such studies and concerns experimental data collected on the old age group.

## II. EXPERIMENT

*a. Material.*—We have chosen old people of both sexes above the age of fifty years. Due to their higher age, most of them had no special work, but they enjoyed retired life. Persons having definite symptoms of illness at the

\*From the Department of Preventive Medicine, Medical College, Keio University.  
Received for publication, June 1, 1933.

time of study were excluded, though some of them had the so-called senile changes of mild nature occurring in the older people, such as high blood pressure, arteriosclerosis, rheumatism, and chronic nephritis. We regarded these changes to be more or less physiologic accompanying age.

The number which we have examined is 94, consisting of 44 males and 50 females. Their ages were as shown in Table I.

TABLE I

| AGE    | MALE | FEMALE | TOTAL CASES |
|--------|------|--------|-------------|
| 50-59  | 13   | 8      | 21          |
| 60-69  | 15   | 16     | 31          |
| 70-79  | 10   | 18     | 28          |
| 80-89  | 5    | 8      | 13          |
| 90-100 | 1    | --     | 1           |
|        |      |        | 94          |

*b. Method of Study.*—These experiments were carried out during the spring and autumn seasons of 1929 and 1930, in order to have more uniform ranges of dry bulb temperature of 15° C. or 23° C. and dry Kata coefficient of 3.0 or 4.5, both of which were measured near the head of the subjects.

The apparatus used for the experiment was a Benedict's respiration apparatus with cot chamber. Every care was taken and the procedure carried out as the inventors<sup>5</sup> had advised.

### III. RESULT AND DISCUSSION

We have summarized our data in Tables II and III. To determine the surface area, we used Takahira's formula<sup>6</sup> which was derived from actual measurements on Japanese subjects, modifying the Du Bois' height-weight formula,<sup>7</sup> since Japanese have a little different proportion of the body structures than do European races.

$$A = W^{0.427} \times H^{0.718} \times 74.49$$

A-----Surface area in square meters  
 W-----Weight in kilograms  
 74.49-----Constant  
 H-----Height in meters

*a. Comparison of Different Age Groups.*—A comparison of the metabolism in each age group is as follows:

Basal metabolism per square meter per hour (Table IV). The difference between the age group of from fifty to fifty-nine and that of the eighty-year group is 3.99 calories (11 per cent) in man, and 3.65 calories (11 per cent) in woman. The decrease in each ten-year period is from 3 to 5 per cent. The decrease being gradual there is no sudden drop of basal metabolism in any age group.

Heat production per square meter per hour and age have the following correlation coefficient:

|        |                  |
|--------|------------------|
| Male   | -0.5173 ± 0.0745 |
| Female | -0.3804 ± 0.0816 |

Though there is a little different correlation coefficient between male and female, both groups have negative correlation. Calculating with these data we found the prediction equations of heat production based on age to be as follows:

$$\begin{aligned} \text{Male} & \quad H = 42.5042 - 0.1202 A \\ \text{Female} & \quad H = 40.2902 - 0.1086 A \end{aligned}$$

TABLE IV

| AGE   | MAN        | WOMAN      |
|-------|------------|------------|
| 50-59 | 36.05 cal. | 34.02 cal. |
| 60-69 | 34.91 cal. | 33.15 cal. |
| 70-79 | 33.16 cal. | 31.90 cal. |
| 80-   | 32.06 cal. | 30.42 cal. |

*b. Sex Difference.*—As Table IV shows, we noticed some difference between the two sexes. It is natural that a female requires less calories per day than a male, as the former usually is smaller in size. However, even when we compare the basal metabolism with body surface area, we notice the same differ-

Calories per Hour per Square Meter

Fig. 1.

ence which is effected, since the constitution and activities of the bodies of male and female are different. In the old age group we found the average value of males to be 34.46 cal. per unit, that of females to be 32.62 cal. This difference can be seen in every age group with an average difference of 5 per cent. This value is coincident with the data reported by Magnus-Levy<sup>1</sup> and Benedict-Emmes.<sup>5</sup>

*c. Comparison Between Young and Old Age Groups.*—Takahira<sup>6</sup> first reported reliable data on the normal standard of basal metabolism of the Japanese. He dealt with the age group between twenty and fifty, and showed the averages to be as follows:

|        |                   |
|--------|-------------------|
| Male   | $37.33 \pm 0.182$ |
| Female | $33.84 \pm 0.301$ |

Our results in the old age groups are:

|        |                   |
|--------|-------------------|
| Male   | 34.46 $\pm$ 0.247 |
| Female | 32.62 $\pm$ 0.242 |

By a comparison of these two averages we find that the old age group has a lower basal metabolism by 6 per cent. The difference between the two sexes is 9 per cent among the young group, while that of the older group is 5 per cent. Here we notice that the difference of metabolism between the sexes becomes smaller with the increase of ages.

*d. Comparison With Other Standards.*—Aub and Du Bois<sup>2</sup> reported that people of from seventy-seven to eighty-three years had a basal metabolism of 35.1 cal., i.e., 10 per cent lower than that of adults. Harris and Benedict<sup>3</sup> reported the basal metabolism of the sixty to sixty-four group as 34.8 cal., i.e., 9 per cent lower than the young group. According to Bailey's data<sup>10</sup> the basal metabolism in the sixty to sixty-five year group is 5 per cent lower than that of the younger group. In the data reported by Boothby and Sandiford<sup>11</sup> the metabolism of a healthy man, aged sixty years, was 37.4 cal., and calculation showed that it was 10 per cent lower than that of their healthy younger group. Krogh<sup>12</sup> modified the Aub-Du Bois standard for ages fifteen to seventy-five and recommended a uniform reduction of 6 per cent from the standard.

We cannot compare these data with each other directly, since the groupings of the ages are different. Curves are drawn for graphic comparison. (Fig. 1.)

Our curve on male groups almost agrees with that of Harris and Benedict in the period of from fifty to fifty-nine, but in female groups it differs a little, and it lies rather near to the Aub and Du Bois' data. In general, our curve drawn with the data of the Japanese resembles that of Krogh, though our data showed less difference between the sexes.

#### SUMMARY

Basal metabolism was measured upon 94 normal Japanese subjects, whose ages ranged from fifty to ninety-three years. It was found that the metabolism of the aged is lower than that of younger people, and it decreases gradually without a sudden drop in any age group. The rate of decrease in each ten-year period is about 3 to 5 per cent. We found that the difference in rates between the sexes in the old age groups is smaller than in the younger groups. Comparing with the other standards, the curve drawn on our data agrees very closely with that of Krogh's modification.

The authors desire to express their appreciation to Professor Yoshio Kusama for much helpful advice and criticism throughout this work.

## THE BLOOD PICTURE IN ORAL INFECTION\*

---

H. H. PETERSON, D.D.S., AND J. L. T. APPLETON, JR., B.S., D.D.S.,  
PHILADELPHIA, PA.

---

THE data which form the basis of this report are the determination of hemoglobin percentage and the blood counts in the same cases of oral infection before and after treatment. These data were abstracted from the papers by Adams, Bryan et al., Bryant and Plevitzky, Burns, Harvey et al., Ivy, Logan, and Toren.

In the original papers only the percentages of the several kinds of leucocytes were given. From these percentages and the white blood cell count, we have calculated the absolute numbers of the several leucocyte types in the cubic millimeter.

Certain shortcomings must be pointed out in order to emphasize the tentativeness of any conclusions reached in this report and in order to point out certain precautions which should attend the collection of fresh data. The clinical condition of the patient, both general and local, should be clearly stated. The indefiniteness of our title is necessitated by the indefiniteness of several of the authors whose papers furnished the data. In the selection of cases, serious and competent effort should be made to limit the observations to patients who are suffering only from one or the other of the types of oral infection chosen for study. Usually no mention was made of the technic used to determine the hemoglobin percentage. This is necessary to reduce observations to a common term before valid comparisons can be made. We have *presumed* that the same technic was used after as before treatment. If this was done, then a comparison is legitimate, although we can form no idea of the absolute amount of hemoglobin present. The time of day at which the white blood cell count was made was generally not mentioned. The possible effects of meals or of exercise apparently were disregarded. A standard procedure is desirable, e.g., the count should be made routinely in the morning before arising and on a fasting stomach. The erythrocyte, leucocyte, and differential counts made before and after treatment in any given case should be made by the same individual, to minimize the "per-

sonal equation." The differential count should be expressed not only in percentages but also in absolute numbers.

Chart 1.

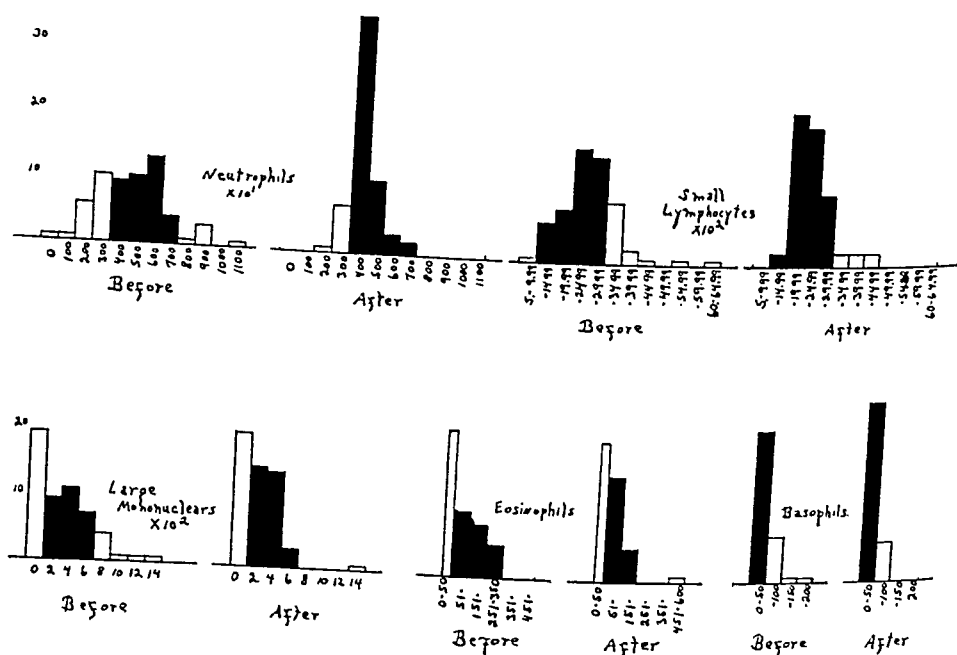

Chart 2.

The data collected are presented in Table I and Figs. 1 to 3. The cases falling within the normal ranges are represented by the blocked-in columns:

those falling outside the normal ranges, by the outlined columns. The number of cases represented by each column is indicated by the numbers at the left. Inasmuch as the number of cases used in constructing the *before treatment* graphs is the same as the number used in constructing the *after treatment* graphs, it was unnecessary to translate these numbers into percentages to permit comparisons.

Chart 3.

### CONCLUSIONS

These are subject to the limitations and criticisms mentioned at the beginning of this paper.

1. Most cases of oral infection do not induce material changes in the blood picture.
2. In some cases, however, departures from normal are seen. Some of these departures are marked. The outstanding changes, when they occur, are:
  - a. An anemia manifested by a lowering of both the percentage of hemoglobin and of the number of erythrocytes.
  - b. Either a leucopenia or a hyperleucocytosis. In the present series, the tendency toward a hyperleucocytosis is slightly the stronger.
  - c. The number and percentage of neutrophils may be above or below normal. In this series, subnormal values appear the more frequently.
  - d. When the small lymphocytes show any change, it is usually in the direction of an increase in their number and percentage. Thus there may be both an absolute and a relative lymphocytosis.
  - e. The number and percentage of large mononuclears, and eosinophiles often run low.

f. The number and percentage of basophiles may run slightly above the normal range.

The numbers of large mononuclears, eosinophiles and basophiles actually noted in doing a "blood count" are so small that it would not be unlikely if later and more extensive studies reversed the statements listed above as e. and f.

3. Following treatment the observed values usually tend to fall within the normal range.

4. This fact supports the views: (a) that the dental infection contributed to the abnormal blood picture, and (b) that the dental treatment applied was more or less successful in combating the infection.

# THE EFFECT OF VARIOUS COLLOIDAL AND CRYSTALLOIDAL METALLIC COMPOUNDS IN NUTRITIONAL ANEMIA OF THE RAT\*

H. L. KEIL, PH.D., AND VICTOR E. NELSON, M.S., AMES, IOWA

KEIL and Nelson<sup>1</sup> have recently made an extensive study of the rôle of copper and certain other elements and amino acids in the regeneration of hemoglobin. This work constituted an elaboration and verification of earlier data by Hart, Steenbock, and coworkers.<sup>2</sup> Goerner<sup>3</sup> states that salts of manganese, as well as of copper, are capable of increasing the hemoglobin of anemic animals when these salts are added to salts of iron. However, he observed that colloidal solutions of manganese and copper in the presence of colloidal solutions of iron have no hematopoietic effect. Myers and Beard<sup>4</sup> found that higher doses of zinc and magnesium retarded blood regeneration.

The experiments recorded in this paper were instituted in order to answer certain questions: First, does manganese act like copper in hematopoiesis? Second, are colloidal Fe and Cu utilized in hemoglobin building? Third, will Fe salts injected intraperitoneally cause regeneration in anemic animals? Fourth, what effect do Zn and Mg salts have on the development of anemia? Fifth, what are the minimum amounts of Fe and Cu required for regeneration of hemoglobin? Sixth, to what extent can different compounds of Cu be utilized in hematopoiesis?

## EXPERIMENTAL

All of the experiments were performed on rats. The milk used for the production of anemia was collected directly into glass containers from pure bred Holstein cows, in order to avoid contamination with copper. The salts were examined spectrographically by a Hilger quartz prism spectrograph and

TABLE I  
DIET: WHOLE MILK COLLECTED IN GLASS

| 2                | 10.6                              | 72.6                        | 16                   |
| 4                | 6.2                               | 42.4                        | 16                   |
| 6                | 5.0                               | 34.2                        | 15                   |
| 8                | 3.8                               | 26.0                        | 13                   |

shown to be pure. Carbon electrodes were used in the spectrographic examination. Hemoglobin content was determined by the Newcomer method. The animals were bled by the tail.

It is evident from the data in Table I that the consumption of the whole milk used in these experiments produces a very marked anemia. Data have

\*From the Laboratories of Physiological Chemistry, Iowa State College, Ames.  
Received for publication, October 5, 1932.

also been obtained which show that anemia results even though iron salts are added to this milk. On the other hand, animals receiving ordinary market milk plus iron salts develop anemia much more slowly. This is due to the fact that ordinary market milk contains more copper than milk collected directly into glass. The amount of copper in market milk is variable.

TABLE II  
EFFECT OF IRON AND COPPER SALTS ON ANEMIA

| TIME<br>IN WEEKS | AVERAGE HB.<br>(GM. PER 100 C.C.) | PER CENT OF<br>ORIGINAL HB. | NUMBER OF<br>ANIMALS |
|------------------|-----------------------------------|-----------------------------|----------------------|
| 0                | 3.7                               | 100.0                       | 12                   |
| 2                | 9.6                               | 259.3                       | 12                   |
| 4                | 13.0                              | 351.0                       | 12                   |
| 6                | 15.2                              | 410.0                       | 12                   |
| 8                | 14.9                              | 402.5                       | 12                   |

Table II shows that copper is very potent in hematopoiesis. The animals were made anemic on whole milk, and when the hemoglobin had fallen to 3.7 gm. per 100 c.c., 0.50 mg. of Fe as  $\text{FeCl}_3$  and 0.05 mg. Cu as  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  were added to the basal diet daily. When the rats were eight weeks of age the average hemoglobin was 402.5 per cent of that at the anemic level.

TABLE III  
EFFECT OF IRON AND MANGANESE ON ANEMIA

| TIME<br>IN WEEKS | AVERAGE HB.<br>(GM. PER 100 C.C.) | PER CENT OF<br>ORIGINAL HB. | NUMBER OF<br>ANIMALS |
|------------------|-----------------------------------|-----------------------------|----------------------|
| 0                | 6.8                               | 100.0                       | 10                   |
| 2                | 6.6                               | 97.0                        | 10                   |
| 4                | 5.2                               | 76.5                        | 8                    |
| 6                | 4.8                               | 70.6                        | 6                    |

Table III shows that the addition of 0.50 mg. of Fe as  $\text{FeCl}_3$  and 0.10 mg. Mn as  $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$  daily to the milk failed to stimulate regeneration of hemoglobin. Manganese therefore cannot replace copper.

TABLE IV  
EFFECT OF COLLOIDAL IRON AND COPPER SULPHATE ON ANEMIA

| TIME<br>IN WEEKS | AVERAGE HB.<br>(GM. PER 100 C.C.) | PER CENT OF<br>ORIGINAL HB. | NUMBER OF<br>ANIMALS |
|------------------|-----------------------------------|-----------------------------|----------------------|
| 0                | 4.5                               | 100.0                       | 10                   |
| 2                | 10.6                              | 235.5                       | 10                   |
| 4                | 11.0                              | 244.1                       | 10                   |
| 6                | 14.7                              | 326.2                       | 10                   |
| 8                | 15.0                              | 333.0                       | 10                   |

Table IV demonstrates that colloidal iron can be utilized in the building of hemoglobin. The colloidal iron was prepared from copper-free  $\text{FeCl}_3$  solution. The latter solution was added to boiling Cu-free water, then dialyzed until free from dialyzable iron. After the animals had developed anemia, 0.50 mg. Fe as colloidal iron and 0.05 mg. of copper as  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  were added to the milk diet. The same results were obtained by the injection of the colloidal iron intraperitoneally.

TABLE V  
EFFECT OF FERRIC CHLORIDE AND COLLOIDAL COPPER ON ANEMIA

| TIME<br>IN WEEKS | AVERAGE HB.<br>(GM. PER 100 C.C.) | PER CENT OF<br>ORIGINAL HB. | NUMBER OF<br>ANIMALS |

The data in Table V show that colloidal copper is also utilized in hemoglobin formation. The copper was nondialyzable. The animals received milk until they were anemic, and then 0.50 mg. of Fe as  $\text{FeCl}_3$  and 0.05 mg. Cu as colloidal copper were added.

TABLE VI  
EFFECT OF COLLOIDAL IRON AND COLLOIDAL COPPER ON ANEMIA

| TIME<br>IN WEEKS | AVERAGE HB.<br>(GM. PER 100 C.C.) | PER CENT OF<br>ORIGINAL HB. | NUMBER OF<br>ANIMALS |
|------------------|-----------------------------------|-----------------------------|----------------------|
| 0                | 4.0                               | 100.0                       | 12                   |

| 14               | 15.1                              | 377.5                       | 12                   |

Table VI shows that colloidal Fe and Cu are utilized for the construction of hemoglobin. The animals developed anemia, and then 0.50 mg. of Fe as colloidal Fe and 0.05 mg. of Cu as colloidal Cu were fed daily. The same results were obtained by injection of the iron and copper intraperitoneally.

TABLE VII  
EFFECT OF INTRAPERITONEAL INJECTION OF IRON SALTS ON ANEMIA

| TIME<br>IN WEEKS | AVERAGE HB.<br>(GM. PER 100 C.C.) | PER CENT OF<br>ORIGINAL HB. | NUMBER OF<br>ANIMALS |
|------------------|-----------------------------------|-----------------------------|----------------------|

| Ferric Chloride  |                                   |                             |                      |
| 0                | 6.8                               | 100.0                       | 18                   |
| 2                | 9.6                               | 141.2                       | 18                   |
| 4                | 10.2                              | 150.0                       | 18                   |
| 6                | 11.0                              | 161.7                       | 17                   |
| 8                | 11.2                              | 164.6                       | 17                   |
| 10               | 10.7                              | 157.2                       | 16                   |
| 12               | 9.2                               | 135.3                       | 16                   |

Table VII shows that Fe as citrate when injected intraperitoneally results in a temporary stimulation of hemoglobin formation. This experiment was performed in order to ascertain if copper was concerned in the absorption of Fe. Copper may play some part in the absorption of iron, but the data show

clearly that the rôle of Cu in hemoglobin regeneration cannot be explained on this basis alone.  $\text{FeCl}_3$  acts like iron citrate although it causes necrosis.  $\text{FeCl}_3$  in glycerol, however, does not have this deleterious effect when injected. The Fe as citrate and chloride was administered at a level of 0.50 mg. of Fe daily.

TABLE VIII  
EFFECT OF ZINC AND MAGNESIUM SALTS ON ANEMIA

| TIME<br>IN WEEKS                    | AVERAGE HB.<br>(GM. PER 100 C.C.) | PER CENT OF<br>ORIGINAL HB. | NUMBER OF<br>ANIMALS |

The data in Table VIII show no effect of Zn and Mg on the development of anemia. The rate of fall of hemoglobin was the same with or without these elements. Two-tenths milligram of Zn as  $\text{ZnCl}_2$  and 0.2 mg. of Mg as  $\text{MgCl}_2$  were fed daily, together with 0.50 mg. Fe as  $\text{FeCl}_3$ . Myers and Beard<sup>4</sup> have

| 12               | 15.1                              | 251.6                       | 12                   |

stated that larger doses of Zn and Mg retard blood regeneration. We therefore believed anemia might develop more rapidly on milk plus  $\text{FeCl}_3$  if these elements were included. The data show this is not the case.

Table IX shows that normal regeneration of hemoglobin is obtained by 0.002 mg. Cu as  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  injected intraperitoneally daily. The animals received milk *ad lib.* and orally 0.50 mg. of Fe as  $\text{FeCl}_3$  daily. This is the smallest amount of Cu that would cause regeneration of hemoglobin to the normal level.

Table X illustrates that regeneration of hemoglobin to the normal level is obtained by injection intraperitoneally of 0.10 mg. Fe as colloidal ferric hydroxide together with 0.002 mg. Cu as  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ . Smaller amounts of Fe failed to cause stimulation of hemoglobin formation to the normal level.

The data in Table XI show that the animal body can utilize various copper compounds in the production of hemoglobin, even though these salts be very insoluble. The character of the anion apparently has no effect on the utilization of the copper.

#### SUMMARY

1. Manganese cannot replace Cu in the synthesis of hemoglobin.
2. Colloidal Fe and Cu are utilized in hematopoiesis.
3. Although the intraperitoneal injection of Fe salts into anemic animals

causes a temporary rise in hemoglobin, it is evident that the main function of Cu is not in the absorption of iron.

4. Zinc and Mg have no effect in the development of anemia.

5. Two-thousandths (0.002) mg. Cu as  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  and 0.10 mg. Fe as colloidal  $\text{Fe}(\text{OH})_3$  are the minimum amounts of these elements that will cause a regeneration of the hemoglobin to a normal level in the anemic rat.

6.  $\text{Cu}_2\text{O}$ , CuS,  $\text{Cu}(\text{OH})_2$ , and CuI are readily utilized by the anemic rat in hemoglobin building. The sulphide is less efficient than the other salts employed.

### EXPERIMENTS IN THE USE OF A MINERAL WATER IN THE MANAGEMENT OF DIABETES MELLITUS\*

LEO K. CAMPBELL, M.D., CHICAGO, ILL.

THE purpose of these experiments was to study the effect of a mineral water when used for long periods in the management of diabetes mellitus. Recently companies bottling many of the highly advertised mineral waters have made extravagant claims for their water of beneficial effects in diabetes mellitus. With this in view the following investigation was undertaken to determine whether or not there was any demonstrable beneficial effect derived from the use of one of these waters.

#### CASE REPORTS

CASE 1.—R. P., male, aged thirty-nine years, first had symptoms of diabetes mellitus at the age of twenty-nine. The disease had run a rapid course, and he had, to the date of the experiments, lived on a quantitative diet with insulin for eight years. He was an intelligent, trained, and experienced patient. His usual diet contained carbohydrate, 105 gm.; protein, 127 gm.; and fat, 183 gm. With this diet he remained in good health but not free of morning glycosuria on an insulin dosage of 75 units.

CASE 2.—H. E., male, aged fifty years, had become diabetic at the age of forty and had required insulin treatment for seven years. This patient was also a very intelligent, trained, and experienced diabetic patient. His customary diet contained carbohydrate, 94 gm.; protein, 74 gm.; fat, 181 gm.; and cal., 2,301, estimated "G,"† or available glucose, 155 gm.; on this diet the urine was usually sugar-free with an insulin dosage of 50 units, divided into 40 in the morning and 10 in the evening.

\*From the department of medicine of Rush Medical College of the University of Chicago and the Presbyterian Hospital.

Received for publication, October 4, 1933.

†The "G," or available glucose, was calculated by the formula, "G" = C + .58P + .10F.

CASE 3.—W. S., male, aged thirty-two years, had first developed symptoms of diabetes mellitus in 1919 at the age of twenty. He first had insulin management in 1923 and went into coma in 1924 at the age of twenty-five. He had been, for seven years, at the time of these experiments on a diet of "G," 175 gm.; cal., 2,275, and insulin, 35 units before breakfast and 16 units before the evening meal. He had remained in good health but not free of glycosuria in the morning and was also an intelligent, well-trained and experienced patient.

CASE 4.—H. D., male, aged forty-five years, had first become diabetic in 1920 at age of thirty-four. By very accurate quantitative management of the diet, he was kept alive until the advent of insulin in 1922 at which time this therapy was started. For nine years and at the time of these experiments, he had been taking 50 units of insulin per day, and he had been in good health but not free of morning glycosuria. His usual diet was "G," 180 gm.; cal., 2,250. He was also a well-trained, intelligent, and experienced patient.

CASE 5.—H. A., male, aged fifty-eight years, first developed diabetes mellitus at age of forty-five. In 1923, at age of fifty years, he was placed on a diet of carbohydrate, 100 gm.; protein, 67 gm.; fat, 156 gm.; "G," 155 gm.; and cal., 2,072, and started on insulin, 32 units before breakfast and 16 units before the evening meal. At the time of these experiments he had been on this program for eight years, had remained in good health; the urine usually was free of sugar. He also was a well-trained, an intelligent, and experienced patient.

All of these patients had been continuously under the observation of Dr. R. T. Woodyatt.

*The Mineral Water.*—The mineral spring water used in these experiments was crystal clear and, according to the analysis submitted by the bottler, contained 120 parts per million of solid material. The distribution of the identified anions and cations was reported as follows:

|                                |    |                                |   |       |                   |
|--------------------------------|----|--------------------------------|---|-------|-------------------|
| H <sub>2</sub> CO <sub>3</sub> | as | CaCO <sub>3</sub>              | = | 38.00 | parts per million |
| Chlorides                      | as | Cl                             | = | 8.00  | parts per million |
| Sulphates                      | as | SO <sub>4</sub>                | = | 18.55 | parts per million |
| Silicon                        | as | SiO <sub>2</sub>               | = | 3.25  | parts per million |
| Aluminum                       | as | Al <sub>2</sub> O <sub>3</sub> | = | 3.52  | parts per million |
| Iron                           | as | Fe <sub>2</sub> O <sub>3</sub> | = | 3.58  | parts per million |
| Calcium                        | as | Ca                             | = | 4.46  | parts per million |
| Magnesium                      | as | Mg                             | = | 1.13  | parts per million |
| Sodium and Potassium           | as | Na                             | = | 24.3  | parts per million |
| Manganese                      | as | Mn                             | = | 0.08  | parts per million |
| Ammonia                        | as | NH <sub>3</sub>                | = | 0.04  | parts per million |
| Nitrates                       | as | NO <sub>3</sub>                | = | 0.02  | parts per million |

The radioactivity of the emanation, when in equilibrium with its parent, from one gallon of this water was reported to be in the neighborhood of  $1.5 \times 10^{-10}$  millicuries.

#### EXPERIMENTS

*Methods of Study.*—Each patient was hospitalized during the periods of study and placed on a diet and dosage of insulin that would permit a slight glycosuria during the entire 24 hours without acidosis. The same insulin preparation was used during all of the experiments. Two control periods were run on each patient with a week intervening. At the end of the second period the patient was discharged from the hospital using his usual diet, dose of insulin, and drinking one gallon of the mineral water each day. After using the water from one to seven months he was again hospitalized, placed on the

diet and dosage of insulin used in the control periods, the water continued, and the urinary glucose determined.

The glucose in the urine was determined by the Folin-Berglund method and polariscopy, the nitrogen by the Kjeldahl method and the creatinine by the picramic acid method. The latter was used for a check on the volume of urine.

*Experiment 1.*—Case of R. P., weight 73 kg. A diet of carbohydrate, 87 gm.; protein, 76 gm.; fat, 199 gm.; "G," 151 gm.; and cal., 2,443, with insulin, 32 units before breakfast, 16 units before the evening meal and 4 units at 3 A.M., permitted a glycosuria without acidosis. The average daily urinary glucose excretion during the first control period was 14.43 gm., and the urinary nitrogen, 11.1 gm. In the second control period the average daily urinary glucose excretion was 13.54 gm., and the urinary nitrogen was 12.8 gm. After he had drunk one gallon of the water per day for seven months, the average daily urinary glucose excretion was 15.76 gm., and the urinary nitrogen was 14.7 gm.

*Experiment 2.*—Case of H. E., weight 60 kg. A diet of carbohydrate, 92 gm.; protein, 54 gm.; fat, 172 gm.; "G," 141 gm.; and cal., 2,132, and twenty-four units of insulin before breakfast and 12 units before the evening meal permitted a continuous glycosuria without acidosis. The average daily urinary glucose during the first control period was 8.61 gm., and the nitrogen, 8.8 gm. In the second control period the average daily urinary glucose was 11.98 gm., and the nitrogen, 10.1 gm. After using one gallon of the water per day for one month, the glucose was 13.14 gm. and the nitrogen, 8.8 gm. After using the water for four months, the average daily urinary glucose was 12.50 gm. and the nitrogen was 10.1 gm. After using the water for seven months, the average daily urinary glucose excretion was 10.34 gm. and the nitrogen, 11.6 gm. In this experiment another control period was run after the water had been discontinued for one month. The urinary glucose then was 7.94 gm. and the nitrogen, 9.8 gm.

*Experiment 3.*—Case of W. S., weight 66 kg. A diet of carbohydrate, 92 gm.; protein, 79 gm.; fat, 187 gm.; "G," 156 gm.; cal., 2,367; and insulin, 28 units before breakfast and 12 units before the evening meal, permitted a slight continuous glycosuria without acidosis. The average daily urinary glucose excretion in the first control period was 9.11 gm. and the nitrogen, 10.5 gm. In the second control period the glucose excretion was 10.01 gm. and the nitrogen, 11.5 gm. After using one gallon of the water per day for three months, the average daily urinary glucose excretion was 8.51 gm. and the nitrogen, 12.4 gm. After using the water for six months there had been no reduction in the daily insulin requirements, and the experiment was discontinued without another period of study in the hospital.

*Experiment 4.*—Case of H. D., weight 65 kg. A diet of carbohydrate, 92 gm.; protein, 79 gm.; fat, 187 gm.; "G," 156 gm.; cal., 2,367; and insulin, 24 units before breakfast and 16 units before the evening meal, permitted a slight continuous glycosuria without acidosis. The average daily urinary glucose excretion during the first control period was 6.84 gm. and the nitrogen, 11.6

gm. During the second control period the glucose was 7.17 gm. and the nitrogen, 12.7 gm. After drinking one gallon of the water per day for three and one-half months, there had been no reduction in the daily insulin requirements, and the experiment was discontinued without another period of study in the hospital.

*Experiment 5.*—Case of H. A., weight 65 kg. A diet of carbohydrate, 92 gm.; protein, 79 gm.; fat, 187 gm.; "G," 156 gm.; cal., 2,367, and insulin, 32 units before breakfast and 16 units before the evening meal, permitted a continuous glycosuria without acidosis. The average daily urinary glucose excretion during the first control period was 12.99 gm. and the nitrogen, 14.7 gm. During the second control period the glucose excretion was 8.17 gm. and the nitrogen, 14.7 gm. After drinking one gallon of the water per day for seven months, there had been no reduction in the daily insulin requirements, and the experiment was discontinued without further study in the hospital.

#### SUMMARY

A study of the effect on diabetic patients of their drinking one gallon of mineral water per day for periods of from one to seven months was made. No beneficial effects could be demonstrated.

The author wishes to thank Dr. R. T. Woodyatt for his valuable advice and assistance during this study.

## THE DYNAMIC CONSEQUENCES OF AN AURICULOPERICARDIAL FISTULA\*

HARRY LANDT, M.D., AND RAYMOND FRIEDMAN, B.S., CHICAGO, ILL.

---

IT IS generally known that pericardial tamponade has a deleterious action on the circulation, and when acute and severe enough may lead to death. Animal experiments, particularly those of Katz and Gauchat,<sup>1</sup> have shown that the action of pericardial tamponade is primarily to interfere with the flow of blood into the intrapericardial veins. Intrapericardial pressures in excess of 300 mm. of oil (saline) lead to circulatory death. It is the fear of establishing fistula with the resulting tamponade effects that has acted as a deterrent to pericardial and cardiac punctures. However, there seems to be an impression that a communication between the pericardium and an auricle is less serious than a communication between the pericardium and a ventricle, the aorta or the pulmonary artery.

In the present investigation an attempt was made to determine the dynamic consequences of producing an auriculopericardial fistula, and in particular to see what risk, if any, was involved in such a procedure.

---

\*From the Cardiovascular Laboratory, Department of Physiology, Michael Reese Hospital. Received for publication, October 30, 1933. Aided by the Frederick K. Babson Fund of the Michael Reese Hospital.

## METHOD

Six dogs, anesthetized with morphine and barbital, were used in this investigation. Artificial respiration was introduced and the chest opened. Chicago blue (15 mg. per kg.) was injected intravenously to render the blood noncoagulable. A pericardial cannula was inserted and connected with a saline manometer. The carotid artery, jugular vein, and a pulmonary vein branch were isolated and cannulated. The first was connected with a mercury U-tube manometer and the other two with saline manometers. After a control record was obtained on a smoked paper kymograph a small opening was made in the pericardium through which a rent about 5 mm. in length was made in the tip of the right or left auricle and the pericardial opening quickly closed. The changes in pressure during and following this procedure were recorded on the kymograph and the data analyzed. As a control 50 c.c. of blood were removed from an animal and quickly injected into the pericardium, and its effects studied.

Fig. 1.—A graph showing the typical effect of an auriculopericardial fistula. Art, is the mean arterial pressure; Jug., Pul., and Per., represent the mean pressure, respectively, in the jugular vein, pulmonary vein, and pericardial sac. Time in five-second intervals. Arrow indicates time of establishment of auriculopericardial fistula. Note the Traube-Hering waves and the homologues in the venous and pericardial pressure curves.

## RESULTS

The results are summarized in Table I and a typical experiment shown in Fig. 1. After the establishment of the auriculopericardial fistula, there was an immediate drop in the mean arterial blood pressure and a corresponding rise in the mean pressures in the jugular vein, pulmonary vein, and in the pericardial sac, following which the pressures tended to level off but continued to change gradually in the original directions until death ensued. The mean arterial pressure just before death approximated 5 to 15 mm. of mercury. At this time the pulmonic venous pressure was found to exceed the jugular pressure in all but one experiment, regardless of whether the fistula was in the right or left auricle. The intrapericardial pressure in no instance rose above 140 mm. of saline following the establishment of the fistula, a figure which is about one-half of that found necessary to cause death with experimental pericardial effusion (Katz and Gauchat<sup>1</sup>). In some experiments the intrapericardial pressure was higher than the intravenous pressure; in others it was lower.

## DISCUSSION

The lack of correspondence of the intrapericardial pressure with the intravenous pressures is in part due to the inability to establish absolutely the correct zero pericardial pressure level. In addition, the cyclic heart action affects the pressure in the pericardial sac in an opposite manner to the extrapericardial venous pressures. For example, ventricular systole lowers the intrapericardial pressure, but raises the venous pressures. In some experiments the last factor may explain the presence of an intrapericardial pressure lower than the venous pressures. The presence of an intrapericardial pressure higher than the venous pressures in other experiments is more difficult to explain. It is conceivable, however, that with a rent in the auricle this part of the wall of the heart may act as a one-way flapper valve, preventing a flow back from the pericardial sac. In this way the pericardial sac might be considered as acting as a maximum pressure manometer.

Tamponade per se cannot be responsible for the serious dynamic consequences of auriculopericardial fistula. Previous workers<sup>1</sup> have found that the pressure in the pericardium causing death in tamponade per se is decidedly greater than the pressure found in the pericardium at the time of death in our animals. This difference cannot be due to the loss of blood, which never exceeded 25 or 30 c.c. in our experiments. Furthermore, the removal of 50 c.c. of blood from the circulation and its rapid injection into the pericardial sac had no appreciable dynamic effect.

The other factor operating in auriculopericardial fistula appears to be the action of the fistula itself, and the following explanation is offered: When the fistula is made, the pressure in the auricle and pericardial sac tend to be equalized, the intrapericardial pressure rises and thereby increases the resistance to onward flow of blood from the extrapericardial veins. This in turn results in a damming up of blood in the extrapericardial veins with a consequent rise in their pressure. The rise in pressure, however, soon reflects itself in a similar elevation in the intrapericardial veins, auricle, and then in the pericardial sac itself. Thus a vicious cycle is started. There is no chance for

<sup>1</sup>Katz, L. N., and Gauchat, H. W.: Observations on Pulsus Paradoxus (With Special Reference to Pericardial Effusions). II Experimental. Arch. Int. Med. 23 371, 1924.

a gradient of pressure to be established between the intrapericardial veins and auricles (and the diastolic pressure in the ventricles) and the pericardial sac, which is essential to prevent stagnation of the circulation and death.

These experiments show that a persistent opening between an auricle and the pericardial sac is associated with danger, even though the amount of bleeding into the pericardial sac be small.

#### SUMMARY

The dynamic effects of a persistent auriculopericardial fistula experimentally produced were studied. It was found that the fistula resulted in a serious handicap to the normal circulation and quickly led to death. This effect is apparently not due entirely to a tamponade action per se but to a decrease in the pressure gradient between the extrapericardial veins and the ventricle during ventricular filling produced by the presence of the fistula.

We wish to thank Dr. Louis N. Katz, at whose suggestion this study was undertaken, for his advice and criticism.

### A TYPHOID-LIKE INFECTION ASSOCIATED WITH AN ORGANISM RESEMBLING *BACILLUS PROTEUS PSEUDOVALERIAE* (DE ASSIS)\*

CHARLES H. NAMMACK, M.D., AND FLORENCE R. BITTMAN,  
NEW YORK, N. Y.

THE case here reported is one of infection with an organism closely resembling *Bacillus proteus pseudovaleriei* (de Assis).

The patient was a man of Canadian birth, a salesman by occupation, aged fifty-eight. The family and history were of no special interest except for the fact that four years prior to the present illness the patient developed hematuria and was operated upon for a papillomatous growth of the bladder. The growth was removed by fulguration in a one-stage operation, and radium seeds were implanted in the base of the growth. Recovery was uneventful, but several months later the patient developed difficulty in urination and was able to urinate only while lying down. It became necessary to remove a stone which had formed around one of the radium seeds and which acted as a ball valve. This procedure was accompanied by severe cystoscopic shock and rigors. During the time that the patient suffered from urinary symptoms prior to operation, he had a considerable number of mild attacks of precordial pain on exertion that had been diagnosed clinically as well as by electrocardiogram as of coronary origin. These symptoms ceased after the operation.

The present illness followed a late lunch which consisted of a spiced beef sandwich. At the time this was eaten the patient thought it had a peculiar taste. He experienced a sense of epigastric distress that became worse the next day. However, on the following day he dined in a speakeasy and had two gin cocktails before dinner. The second day he had a sense of dull epigastric ache. On the third day he had severe chills lasting several hours followed by fever and sweating. During the next two weeks the symptoms became more severe and the chills and fever more frequent. There was no regular interval between the attacks.

\*From the Department of Pathology and the Fourth Medical Service of Bellevue Hospital. Received for publication, November 9, 1933.

Anorexia and prostration were marked, and the patient lost weight rapidly and entered into a typhoid state. At this point he was admitted to the Fourth Medical Service at Bellevue Hospital. At the time of admission abdominal pain on the right side was the predominant symptom. Examination of the abdomen was negative.

Shortly after admission the patient became jaundiced. The van den Bergh test was positive and the stools were clay colored. There was rigidity in the right upper quadrant and some tenderness in the region of the gallbladder. The blood chemistry was negative. The patient began to have steady hiccoughing, and the urine was found to contain pus. Several infusions of glucose were given intravenously. The blood chemistry now showed nonprotein nitrogen 75, sugar 120, and creatinine 2.5. Blood cultures taken shortly after admission were positive and a gram-negative bacillus was found in the blood. The Widal reaction was negative. The same organism was isolated from the feces. The temperature curve gradually subsided and after a stay of three months in the hospital the patient went to his home. Following his return to New York in October he complained of severe pains in the muscles of the upper thorax. These pains were so severe as to require the use of a sedative. The x-ray of the chest and spine were negative, and the patient was given a series of heat and ultraviolet ray treatments followed by complete cessation of the pains. At the present time he is in good health and has regained weight and strength.

During bacteriologic studies of blood cultures from this patient, we isolated a bacillus which appears to be closely similar to the *Proteus pseudovaleriei* isolated by A. de Assis in Brazil in 1926.<sup>1</sup>

Blood cultures were made in vitamin broth and nutrient agar pour plates. The first culture, taken April 29, 1932, the day after admission, showed a gram-negative motile bacillus in both broth and plates after twenty-four hours. Another culture was taken May 7, eight days later, which was also positive. A third culture, taken May 26, was sterile.

Agglutination tests: Normal saline suspensions of the growth on an eighteen-hour agar slant and an eighteen-hour broth culture were tested with dilutions of 1:50 and 1:100 specific typhoid and paratyphoid A and B sera. No agglutination occurred.

Repeated Widal tests of the patient's serum proved negative with typhoid and Para A and Para B.

On May 26, nineteen days after this organism had been recovered from the patient's blood, the patient's serum was tested with the organism. Serum agglutinated through 1:2,500, negative 1:5,000. On repeating the test complete agglutination was found in 1:3,200, negative 1:5,000. Tested with typhoid Para A and Para B the serum again proved negative.

Stool culture of June 16, seventeen days after defervescence, on Endo plates showed a single colony which resembled morphologically and culturally, the organism isolated from the blood, and agglutinated with the patient's serum of May 26 through 1:3,200, negative 1:5,000.

These results showed that the organisms isolated from the blood and from the stool were identical, and the fact that it agglutinated with the patient's serum in a dilution of 1:3,200 showed that it was the cause of the infection.

In 1910, Rottkay<sup>2</sup> described a fatal case of typhoid-like disease from which he was able to recover an organism related to *B. Proteus vulgaris* (Hauser) which he isolated from the feces and after death from the spleen and ileum.

Boycott<sup>3</sup> in 1906 isolated from the stool of a case of atypical typhoid, two strains of Valerei which did not agglutinate with the patient's serum. This patient's serum was agglutinated with Para B. although no paratyphoid organisms were isolated from the stools.

De Assis in 1926 recovered an organism from the blood of a case of typhoid-like infection on two occasions, that strongly agglutinated with the patient's serum, but did not agglutinate with typhoid, Para A and Para B. He called his organism *Proteus pseudovaleriei*.

## DESCRIPTION

Morphology: a gram-negative actively motile bacillus of varied size, from coccoid to the longer threadlike forms, morphologically resembling the typhoid bacillus.

Subcultures were made on the following media:

- a. Nutrient agar slant showed a moist spreading grayish white fluorescent growth.
- b. Broth showed a rapid growth, of even turbidity, with the formation of a collar or ring at the surface, and sediment after forty-eight hours. No pellicle was formed.
- c. Blood pour plates showed greenish colonies similar to typhoid.
- d. Endo plates showed bluish transparent colonies similar to typhoid. Broth cultures kept in the ice box a week or more and subcultured on endo showed presence of "phage plaques."
- e. Triple sugar agar slants were inoculated with colonies from Endo plates and showed acid "butt" with gas production and a colorless slant similar to the paratyphoid-enteriditis group.
- f. Litmus milk showed acid in twenty-four hours but was not clotted. Later it became decolorized, with partial coagulation. No digestion or peptonization.

These cultures were transplanted to various carbohydrate fermentation broth tubes containing Andrade as the indicator. Dextrose, levulose, maltose, mannite, saccharose, xylose, salicin, arabinose, raffinose, and glycerol were fermented with gas production. Lactose was not touched until after seven days, then it gave a faint acid reaction. Dextrin showed slight reaction after seventy-two hours. No gas was produced in either lactose or dextrin. Inulin and dulcitate were not touched. These fermentation tests were repeated twice and all three reactions on the same lot of media proved the same. From 50 per cent to 100 per cent gas was formed.

## PATHOGENICITY

We inoculated two 250 gm. guinea pigs intraperitoneally with 0.5 and 0.75 c.c. of eighteen-hour-broth culture. After three hours the pigs became quiet and drowsy, did not eat, and the hair looked roughened. Eighteen hours later they showed signs of prostration, had not eaten any food, and when placed on their backs were barely able to right themselves. Within twenty-four hours both pigs were dead. The same organism was recovered in pure culture from the peritoneum and heart's blood of both pigs.

There was a considerable amount of injection at the site of the inoculation. The peritoneum contained about 10 c.c. of mucoid fluid. The mesentery and omentum were injected. The suprarenal glands were hemorrhagic. The spleen of one pig was slightly enlarged, the gallbladder was quite distended.

## DISCUSSION

The biologic characteristics of our organism places it in the genus *Proteus*. In 1906 Boycott described a bacillus (*valeriei* 21) which our organism closely

resembles in motility and fermentation, although our bacillus does not ferment dextrin and dulcitol; while his does not ferment salicin, and does not touch lactose at all. De Assis, in 1926, described a bacillus which our bacillus resembles, except that ours ferments saccharose, raffinose, and glycerol, while his did not. Our bacillus resembles Castellani's *Proteus asiaticus* in fermentation, but differs in its reaction on litmus milk, and in motility. Our strain resembles Hauser's vulgaris in its reaction on saccharose, dextrin, dulcitol, and glycerol, but it does not resemble it in its reaction on arabinose, salicin, raffinose, mannitol, or litmus milk. The difference in the reaction on dextrin may be due to the variation of dextrin.

Our organism resembles the *Proteus pseudovaleriei* of de Assis in its fermentation reactions more closely than it does Hauser's Vulgaris or the Valerei of Castellani or of Boycott, and by the fact that his patient, like ours, recovered, while all of the others died.

#### SUMMARY

An organism isolated from two different samples of blood and from the stool of a patient with a typhoid-like infection, strongly agglutinated with the patient's serum but did not agglutinate with typhoid, Para A or Para B. This organism may be classed with that of de Assis.

# LABORATORY METHODS

---

## AN IMPROVISED BACTERIOLOGIC INCUBATOR\*

---

ROY A. HANKEY, MICROBIOLOGY D., BUTLER, IND.

---

A HIGH-PRICED bacteriologic incubator costing from \$100.00 to \$300.00 can be improvised at the very moderate cost of \$20.00 or less with no sacrifice in the quantity or quality of the results to be obtained from its use. The improvised incubator can be assembled in less than fifteen minutes with only four articles that can be easily and quickly obtained, especially for those who live in a city.

A small, used refrigerator made to hold 25 pounds of ice makes a very satisfactory sized cabinet for an incubator large enough to do the bacteriologic work of a moderately large hospital. I assembled an excellent incubator, using a top icer of the above size which was purchased from a storage company for \$1.50. The refrigerator was as good as new and the factory finish on it was still good.

The second article needed for the construction of the incubator is an electric heating element and regulator or electric thermostat. This can be purchased from any good laboratory supply company for not more than \$16.00 and large enough to keep the entire inside of the refrigerator at 37° C. or body heat.

The third article needed to make the first class incubator is an accurate thermometer with which to regulate the electric thermostat and check the temperature of the incubator when in use. The thermometer can be obtained from the same supply company as the thermostat for a dollar or less or a suitable one can be obtained at a drug store.

The fourth article needed is a one-holed stopper which can be obtained from the supply company.

With these articles at hand one is ready to begin assembling the incubator. First open the door to the refrigerator and remove the tube connecting the ice compartment with the storage compartment by raising up and pulling out on the bottom of the tube. This leaves an opening down through the bottom of the refrigerator. Next, the thermostat is placed on the lower shelf in the left rear corner and the electric cord will just be in position to go down through the hole in the lower shelf, but first the electric connection will need to be temporarily removed as the hole in the floor of the refrigerator is not large enough to pass the connection through. After the cord has been

---

\*From the Hankey Laboratory.  
Received for publication, October 23, 1933.

put through the floor, the electric connection can be replaced and made ready to plug into a wall socket supplying 110 volt current.

If a laboratory type of thermometer is to be used, an inch hole should be drilled through the top door and a cork with a hole made through it the size of the thermometer can be inserted in the hole. The thermometer is then suspended with the bulb well within the refrigerator by passing it through the stopper so that the mark for body heat or 98.6° F. is well above the outside of the cabinet. Any accurate thermometer may be used by placing it on the shelf inside the refrigerator and the readings taken quickly upon opening the door or before the thermometer has time to change enough to be of any importance. However, for greater accuracy the laboratory thermometer through the pierced wall is recommended, so that the temperature can be read without opening the door.

For the proper growth of aerobic organisms a half-inch hole should be drilled through the top near the center for a small amount of ventilation to maintain the oxygen supply even during prolonged incubations.

You are now ready to start the regulation of the thermostat for the desired temperature by plugging into the 110 volt current and closing the doors. Keep a frequent watch of the rising temperature and as soon as the desired temperature is attained take notice if the heater bulb is still lighted up, by observing through the ventilator opening in a darkened room or by opening the door slightly. If it is still lighted up open the door and turn the knulled knob of the regulator on the thermostat to the left until the light goes out. Then watch the temperature again. If it should go too low the next time turn the regulator to the right but let sufficient time elapse to insure even distribution of the heat before making any changes in regulation. Let the incubation continue for some time after the right temperature is attained to make sure that an exact adjustment has been made. You have now completed a very efficient and serviceable incubator.

If it is desired to use the incubator on 32 volt current, purchase the thermostat without the heater bulb and replace same with a 100 watt 32 volt bulb and regulate as above.

# DETERMINATION OF THE $P_H$ OF NORMAL AND MALIGNANT TISSUES WITH THE GLASS ELECTRODE AND VACUUM TUBE NULL INDICATOR\*

H. M. PARTRIDGE, PH.D., J. A. C. BOWLES, PH.D., AND  
ANNA GOLDFEDER, M.D., NEW YORK, N. Y.

IN A previous communication<sup>1</sup> the authors have discussed the results of  $P_H$  measurements with the glass electrode on certain normal and tumor tissues. It is the purpose of this paper to describe the method. The apparatus used requires comparatively little electrical shielding and is simple, stable and semiportable in nature.

## METHOD

The method for measurement of the potentials developed by the glass electrode cell was the conventional Poggendorf circuit with the exception that a vacuum tube null instrument was used. A Leeds and Northrup type K potentiometer was used to furnish the known opposing potential.

## THE NULL INDICATOR

The present circuit differs from those previously described by the authors<sup>2, 3, 4</sup> mainly in that the bias and free grid-adjusting resistors are in parallel with the power supplies instead of in series. This arrangement gives equal stability with improved sensitivity and simplicity of operation.

Fig. 1 with the list of circuit constants fully explains the electrical values.

## OPERATION

Potentiometer  $P$  is adjusted to furnish correct opposing potentials in the usual manner.

To adjust the null apparatus, batteries  $A$  and  $C$  are connected and allowed to operate for twenty minutes or a half hour in order that the various chemical and thermal equilibria may be established.

With no connection at jack  $S$ ,  $Rg$  is set so that galvanometer  $G$  gives no deflection when tapping switch  $T$  is pressed. Plug  $B$  is now inserted in  $S$ , and  $Rb$  is adjusted until  $G$  again gives no deflection when  $T$  is depressed.  $B$  is removed from  $S$  and replaced by  $E$  which completes the external cell-measuring circuit.  $P$  is adjusted until  $G$  again gives no movement, and the E.M.F. of cell  $HR$  is read from  $P$ .

## SHIELDING

Under ordinary conditions when glass electrodes with resistances of less than 15 megohms are used, no shielding of the external circuit is required.

\*From the Chemical Laboratories of the Washington Square College of New York University and the Achells Laboratory of the Lenox Hill Hospital, New York, N. Y.  
Received for publication, October 16, 1933.

As indicated in the list of constants the tubes  $VV$  are shielded electrostatically (and to a slight extent, electromagnetically) to aid in setting  $R_g$  when the grid circuit is open. The general rule for shielding is obviously that when the electrical strays reach a magnitude comparable with the currents flowing in the input measuring circuit, screening is necessary. A connection to ground is sometimes helpful but for the present work was unnecessary.

# SENSITIVITY, STABILITY, LEAKAGE

With the circuit described which includes a portable galvanometer, a sensitivity of from 2,500 to 4,000 mm. per volt is obtained. In other words, when the bridge is out of balance by an amount representing 0.01  $P_H$  a deflection of from 1 to 2 mm. is noted on galvanometer  $G$ . Tube characteristics and resistance conditions in the input circuit cause considerable variation in this factor.

Fig. 1.—Schematic circuit for glass electrode E. M. F. measurements. Circuit constants. *Shield*, Metallic enclosure for tubes to assist in adjusting circuit when the grid is "free." *H*, Haber type glass electrode. Corning Glass Works' 015 glass. Resistance 5-12 megohms. Diameter of bulb approximately 8 mm. *R*, *Ba*. . . . . Conventional method for securing known potential. . . . . small radio type. *S*, Jack to fit *E* and *B*. *V*, *V*, "Duovac" 1.1 volt 270 . . . . . triodes. *A*, Battery of 12 large size flashlight cells, approximately 18 v. . . . . midtapped resistance. *Rf*, Filament resistor 1.9 ohms. . . . . 2-volt storage cell of approximately 50 ampere-hour capacity. *Rbg*, . . . . . tor equipped with four movable contacts. *Rb*, *Rg*, Variable resistors of . . . . . type, 500 ohms each. *Rp*, Plate resistor, 3,000 ohms. *MA*, Plate circ . . . . . 0-1 or 0-1.5. Not necessary for actual operation but helpful in mal . . . . . Portable pointer type galvanometer, resistance 1,100 ohms; sensitivity 8 mm. per microampere. *T*, Tapping switch.

Mechanically, the apparatus is stable, and for ordinary conditions no cushioned mounting is necessary. Electrically, the drift is very small when the various thermal and chemical equilibriums have been reached—often less than the equivalent of a millivolt per hour. The room temperature, of course, must remain constant since the power supplies have temperature coefficients. That this is a major factor in the drift characteristic was demonstrated by allowing the room temperature to change slowly and taking time-room-temperature and time-drift relationships. The curves obtained were similar in shape with the drift change following the thermometer change with a delay of from twelve to fifteen minutes.

Leakage difficulty is negligible if care is taken to have the connection between  $H$  and  $E$  short and well insulated. For the latter purpose, dry wooden

supports have always been found adequate. Results with the equipment when used on a constant system are reproducible to a few hundredths of a millivolt.

### ELECTRODES

Haber type electrodes *H* made from Corning 015 glass were used having diameters of approximately 8 mm., and resistances ranging from 5 to 12 megohms. Some of the electrodes were filled with a Clark and Lubs buffer ( $P_H$  about 2) saturated with quinhydrone. Others were filled with  $N/10$  HCl (approximately) saturated with quinhydrone.<sup>6</sup>

Fig. 2.—Electrode assembly shown in detail. *H* is the glass electrode (see circuit constants for Fig. 1) containing buffer or HCl saturated with quinhydrone; *R* is a calomel Ball type reference electrode. The electrical contact to each electrode is made by a fine platinum wire which is sealed into a glass capillary. A copper wire soldered to each platinum wire makes contact with the measuring device. The electrode vessel *X* is fixed rigidly to the wooden base *W* by the collar *Y* and socket *Z*, both of spring brass. Electrodes *R* and *H* are clamped in position above *X* and contacts with the material to be measured are secured by raising the assembly *WXYZ*. The latter is held in place by thumb screw *T*.

The complete electrode assembly is shown in Fig. 2.

The reference electrode *R* was the general type described by Ball.<sup>8</sup>

The complete electrode combination was as follows:

|    |                   |                         |       |                            |               |    |

|----|-------------------|-------------------------|-------|----------------------------|---------------|----|

### CALIBRATION OF GLASS ELECTRODE

The glass electrode was calibrated before and after each determination against Clark and Lubs buffers.<sup>9</sup> The values used for calibration were 6.55, 6.98, 7.14, 7.35, 7.53, and 7.76. These were compared by both the hydrogen and quinhydrone electrodes.

We observed, as did Britton and Robinson,<sup>7</sup> that the glass electrode within this  $P_H$  range adheres to its calibration potentials for several hours. These observers found their electrodes in this region to come to equilibrium almost instantaneously, whereas, in our work about four minutes were required before a steady potential was attained. This can hardly be attributed to time to dissipate a charge; for after equilibrium was attained, the glass electrode was removed from solution, then replaced and a reading again taken which was always found to be the same as that at equilibrium.

The electrode was cleaned by washing with distilled water of the same temperature as the electrode. It was dried by carefully wiping with jagged edges of torn filter paper.

### $P_H$ OF TISSUES

Different normal and cancer tissues from rats and mice were used. The animal was killed, the tissue immediately removed, quickly macerated and

Fig. 3.—Mouse with Tumor 63.

placed in electrode vessel (Fig. 2) and forced into the connecting arm so that contact could be made with the reference electrode  $R$ . As soon as the glass electrode bulb was completely covered with tissue, a thin layer of paraffin oil was added and E.M.F. measurements taken. The system came to equilibrium within three or four minutes and remained constant for approximately another three minutes, after which there was the usual slow drift toward a lower  $P_H$ . The  $P_H$  values of the tissues were obtained directly from the calibration curve (see Fig. 3). With the apparatus in readiness the  $P_H$  measurements were completed within eight minutes after the death of the animal.

In Tables I, II, and III are some results obtained by the method outlined.

Furusawa and Kerridge,<sup>10</sup> and Carlström, Ege, and Henriques<sup>11</sup> obtained average  $P_H$  values of 6.89 and 6.88, respectively, for tissues from leg muscles of normal rats. Our results for similar normal tissues are therefore in close agreement.

#### SUMMARY

A method has been described for the determination of  $P_H$  in normal and malignant tissues by means of the glass electrode. The electrical apparatus is comparatively simple, stable and semiportable. For the normal animal tissues compared, our results are in close agreement with other workers.

## THE RECORDING ELECTRODYNAMIC BRAKE BICYCLE ERGOMETER\*

L. E. A. KELSO, B.S., AND FRANCES A. HELLEBRANDT, M.D., MADISON, WIS.

---

WE HAVE elsewhere briefly described a bicycle ergometer which has since been rebuilt, further improved, and modified.<sup>1</sup> It fulfills the need for a work machine which not only provides a satisfactory brake and accurately measures work done, but which simultaneously records the constancy of the output and the speed of working. These are factors of importance in physiologic studies of exercise so far as the cost of muscular work is related to the speed and steadiness with which it is performed. The constancy of the output is a variable hitherto unmeasured by the ergometers in common use. The chief purpose of this communication is to present the circuit diagram of the new recording electrodynamic brake ergometer and to describe its method of calibration.

*Principle.*—The principle of the electrodynamic brake resides in the fact that a separately excited direct current generator is the load. When a generator armature is rotated and the field is excited, a voltage is generated. If the armature is then connected to a resistor, a current will flow. This current reacting against the field magnetism develops a counter torque or braking effect. The work done in unit time is the torque multiplied by the distance it moves, or the rate of work in watts is the generated voltage times the current flowing.

*Description of the Apparatus.*—As constructed, the ergometer consists of a standard woman's bicycle frame from which the wheels and handlebar have been removed, mounted on a portable supporting structure along with the necessary accessories. These consist of a generator, storage battery, load resistor, field control resistor, ammeter, voltmeter and electrical revolution counter. The set-up is illustrated in Figs. 1 and 2.

\*From the Departments of Physiology and Electrical Engineering, University of Wisconsin.  
Received for publication, September 20, 1933.

The generator is a 12 volt Dodge automobile starter. The series winding is disconnected and the shunt winding is connected for separate excitation. The generator is directly driven from the main sprocket which has 100 teeth. There are 10 teeth on the generator sprocket, giving a generator to pedal speed ratio of 10. A fly wheel is affixed to the generator shaft to assist in the maintenance of constant speed.

The load resistor is of advance wire which has a resistance practically independent of temperature. The resistor is connected across the armature

Fig. 1.—Photograph of the recording electrodynamic brake bicycle ergometer. *A*, ammeter; *V*, recording voltmeter; *T*, timer; *C*, electric clock; *FR*, field control resistor; *SB*, switch board; *LR*, load resistor; *F*, flywheel; *G*, generator; *MS*, main sprocket. The rotating switch for the electrical revolution counter may be seen just above the hub of the main sprocket. The storage battery and charger are located to the right of the generator and the flywheel.

with a switch  $S_3$  which may be opened for testing purposes. It is made up of 6 coils of wire in parallel so that the value of the load may be changed for subjects of widely different strengths.

The voltmeter is a 15 volt graphic recording instrument. The clock is driven by a Warren self-starting synchronous motor, and has chart speeds of 3 inches per minute and 3 inches per hour. It is started and stopped by switch  $S_4$  which is mounted within easy reach of the subject. The lever that

changes the chart speed may also be reached by the subject. The recording needle is large and easily visible, so that the meter is distant reading at all times and may be made recording at will.

A 12 volt storage battery is used to supply the current for the field excitation, the revolution counter and the timer. For convenience a portable charger is mounted on the platform which holds the battery, and it may be charged during long riding bouts. The circuits are so arranged that the battery may also be used to furnish power to operate the generator as a motor for calibration purposes.

The ammeter is a 15 ampere distant reading instrument. It indicates the value of the excitation current when the ergometer is in use and the value of

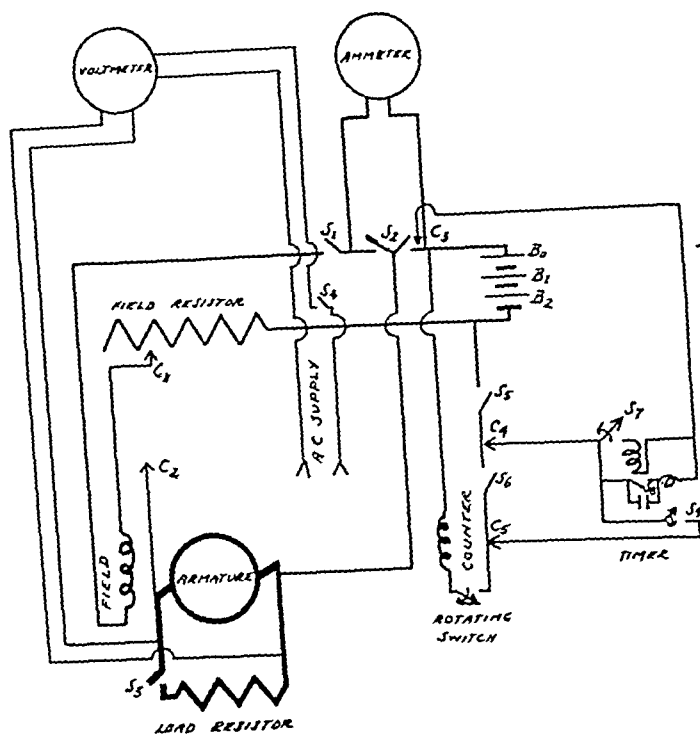

Fig. 2.—Circuit diagram of the electrodynamic ergometer.

the current to the armature for motor action during calibration procedures. Field currents from 1 to 7 amperes are those normally used. Switch  $S_1$  is in the field circuit. The double throw switch  $S_2$  is used to send the armature motor current direct to the armature, or through the ammeter in parallel with the field current. The ammeter may thus be made to indicate either the field current alone, or the combined field and motor armature currents.

The field current is controlled by a 20 inch, 12 ampere, 8.5 ohm resistor with a sliding contact,  $C_1$ . This field resistor is mounted in front of and close to the operator, so that it may be reached and controlled while riding. The moving contact,  $C_2$ , may be connected to various points on the battery for motor operation purposes.

The revolution counter is operated by an electromagnet. A rotating switch on the main sprocket makes contact once each revolution. With switch  $S_6$  closed,  $S_5$  starts and stops the counter. It may be automatically kept in and out of service by a timing device parallel with  $S_6$ . A three conductor cable connects the timer with the ergometer. The contacts are made as indicated by  $C_3$ ,  $C_1$ , and  $C_5$ . When  $S_6$  is open, the timer is in control of the counter, but when  $S_6$  is closed, the timer is inoperative. With  $S_5$  open, both the counter and the timer are out of service.

In the timer itself,  $S_7$  is a switch operated by an electric clock and closed every fifteen seconds. The current through  $S_7$  operates a relay that closes  $S_5$ . The current through  $S_8$  operates an electromagnet that rotates a drum  $\frac{1}{100}$

Fig. 3.—Curves for the conversion of load terminal voltage into rate of working and for the estimation of pedalling rate under various field current and load terminal voltage conditions.

of a revolution. The switch  $S_8$  is paralleled by a condenser to cut down sparking. The contact on the drum,  $S_9$ , is opened and closed for different lengths of time depending upon the calibration of insulating strips on its surface.

**Calibration of the Ergometer.**—The output of the subject is the input to the ergometer. This input is composed of the stray power losses and the armature generated power. For any speed and field current and no armature current, a certain amount of power is required to run the ergometer. This power is assumed to be independent of armature current and is called the stray power loss. The armature developed power is the product of the armature current and the generated voltage. It is possible to determine the value of these losses for any load terminal voltage. Their sum plotted against load

terminal voltage is the calibration curve of the instrument. This is presented in Fig. 3, the speed vs. load terminal voltage curves being plotted on the same sheet.

The stray power losses are determined by making a series of runs, varying the speed but keeping the field current constant for each. The speed, field current, armature voltage, and armature current are recorded. The stray power losses are then calculated and the corresponding load terminal voltage determined. The stray power losses for the various speeds and field currents are then spotted on a graph and a composite curve drawn which gives the loss for any voltage.

The armature developed power is calculated in the following way: The generated voltage is the sum of the load terminal voltage, the brush drop, and the resistance drop of the armature proper and the leads. The armature current is the load terminal voltage divided by the load resistance. The load resistance is constant and is independent of temperature. The brush drop is assumed constant at 0.5 volt. The resistances of the armature and leads vary with the temperature, but since they are small, the error due to temperature change is small.

The resistance of the armature, the leads and the load resistor was determined, employing the volt ampere method, and using currents over the range that would be obtained under load conditions. The brush drop was estimated by plotting a series of curves of no load terminal voltage vs. speed, for constant field current. These curves were projected back to the zero speed line, their intersections with this line being taken as the brush drop. In making the no load runs the generator was operated as a motor. Switch  $S_2$  was opened,  $S_2$  was closed up,  $S_1$  was closed, the field current  $I_f$  was adjusted to some value, and contact  $C_2$  was connected to some point on the battery, as  $B_1$ . The apparatus now operates motor action at no load, and the input to the armature is the stray power losses plus a small loss due to brush drop and armature resistance. The field current was again adjusted and the values  $B$ ,  $E_t$ ,  $I_f$ , and R.P.M. were recorded.  $S_2$  was closed down. The armature and field currents both pass through the ammeter. They were recorded as  $I_{(a + f)}$ .  $S_2$  was closed up and a new contact made on the battery, and the data were obtained over the range of speeds to be used. Then the entire procedure was repeated for all values of field current over the range to be used.

The stray power loss is the generated voltage times the armature current. The generated voltage is related to the no load terminal voltage by the following equation:  $E_g = E_t + (0.5 + I_a R_a)$ .

The no load data for the stray power calculations were arranged as follows:

|   |       |       |               |       |        |      |            |
|---|-------|-------|---------------|-------|--------|------|------------|
| B | $E_t$ | $I_f$ | $I_{(a + f)}$ | $I_a$ | R.P.M. | S.P. | $E_{load}$ |
|---|-------|-------|---------------|-------|--------|------|------------|

where  $B$  is the connection on the battery,  $E_t$  is the no load terminal voltage,  $I_f$  is the field current,  $I_{(a + f)}$  is the sum of the field and armature currents,  $I_a$  is the no load armature current, R.P.M. is revolutions per minute, S.P. is stray power loss, and  $E_{load}$  is the load terminal voltage for a generated voltage of the same value as the generated voltage for the corresponding  $E_t$ .

For any stray power loss the generated voltage is calculated as before. The load terminal voltage is related to the generated voltage by the following equation:

$$E_g - 0.5 = E_t (1 + \frac{R_a}{R_{load}})$$

The armature developed power is the product of the armature load current and load generated voltage. This is expressed in terms of load terminal voltage by the following equation:

$$W = \frac{E_t^2}{R_{load}} (R_L + R_a) + \frac{0.5 E_t}{R_{load}}$$

The watts are changed to Kg.m./min. by the following equation:

$$\text{Kg.m./min.} = W(6.15075).$$

*Criticism of the Instrument.*—The possible sources of error are, (a) stray power losses, (b) armature  $I^2R$  losses, and (c) brush drop loss. These are all small and their possible variation from the mean is also small. Their total effect is assumed to be less than errors due to the inability of the subject to keep the voltage constant, and may therefore be neglected.

The validity of this instrument has not been determined. It purports to measure the output of mechanical work performed by human subjects. The comparison of the results obtained with some outside criterion is difficult to effect, and further, is unnecessary because the instrument is built upon a brake principle of proved characteristics already demonstrated and long used with success in engineering.

The degree to which the measuring devices for the determination of mechanical work, constancy, and speed give invariable readings under identical conditions is high. For a given field current and pedalling rate, the load terminal voltage is always the same, irrespective of the environmental conditions and the experience of the operator. Constancy and speed are measured by synchronized, electrically driven clocks. Under identical field currents and load terminal voltages, the speed of pedalling may be well duplicated, both during protracted bouts of exercise and during pieces of work performed on different days. For example, at a given field current an experienced rider holds the voltmeter needle at the prescribed point with such accuracy that the speed of pedalling, estimated for one minute at five-minute intervals during a one-hour period of exercise, will not vary by more than one revolution per minute plus or minus, and will remain at the modal R.P.M. 83 per cent of the time.

We believe this measuring device is especially good because of its objectivity and administrative economy. The recording voltmeter graphs the constancy of the performance and automatically records the data necessary for the calculation of the rate of working. The speed of pedalling is also automatically counted at any desired intervals during the exercise. The apparatus is movable and may be used by a subject without the assistance of an operator.

*Principles for the Selection of Load and Speed Conditions.*—Table I presents the rate of working and the speed of pedalling under a wide range of

field current and load terminal voltage variations. The exercises performed under these loads and speeds have been classified physiologically as to their severity. In Table II this classification is presented along with the data for performing the different exercises in various gradations on the electrodynamic brake bicycle ergometer.

| 740                                                                    | 104    | 2       | 5     |
| 1031                                                                   | 88     | 3       | 6     |
| 1031                                                                   | 124    | 2       | 6     |
| 1366                                                                   | 104    | 3       | 6     |
| 1366                                                                   | 84     | 4       | 7     |
| 1749                                                                   | 120    | 3       | 7     |
| 1749                                                                   | 84     | 5       | 8     |
| 1749                                                                   | 98     | 4       | 8     |
| Exhaustive Exercise                                                    |        |         |       |
| 740                                                                    | 73     | 3       | 5     |
| 1031                                                                   | 88     | 3       | 6     |
| 1031                                                                   | 72     | 4       | 6     |
| 1366                                                                   | 84     | 4       | 6     |
| 1366                                                                   | 74     | 5       | 7     |
| 1749                                                                   | 84     | 5       | 7     |
| 1749                                                                   | 72     | 6       | 8     |

The exact load and speed conditions to be selected depend upon the age and the development of the individual subject. The child does not possess the muscular strength to perform exercises at the upper ranges of field cur-

rent. Nor can the upper ranges of speed be well borne. The young adult is better suited than the subject in any other age group to carry on violent exercises of speed. He can be expected to perform creditably under the low field current and high voltage conditions associated with the highest pedalling rates. Muscular power is at its height during middle age and the exhaustive exercises of endurance at high voltage and field currents are then well tolerated. Table II is based upon the performance of strong, healthy, young adult women in training for physical education. At a given rate of working, they invariably prefer an exercise with a low field current and high speed of pedalling to one with a high field current and a slower pedalling rate. Exercises of speed are performed well, but these subjects do not possess the muscular power to pedal against a strong resistance. The limitations of the table are obvious. Mild exercise for one individual may be moderate for another. Under certain speed and load conditions an exercise may be easily borne for ten minutes, but carried on for an hour, it becomes exhaustive.

*Operation of the Ergometer.*—Having decided upon the field current and the load terminal voltage with the aid of the tables, close switch  $S_3$  and switch  $S_1$ , leaving  $C_2$  disconnected. Adjust the field current to the proper value by moving the slide contact on the field resistor. The proper selector on the timing device is connected at  $S_6$  and the drum is rotated until it has at least one movement to make before  $S_2$  contacts. The roll mechanism of the voltmeter is started by closing the clock motor control switch  $S_1$ . The revolution counter is read, pedalling the bicycle is begun, and  $S_2$  is closed. The subject now has fifteen seconds or more to get to stable conditions before  $S_2$  contacts and the revolution counter begins to operate. The counter will operate for the chosen time and will then be automatically disconnected. The reading of the counter is then recorded, and the subject continues to ride and record to the end of the run.

*Comment on the Uses of the Instrument.*—The ergometer has thus far been used for the following four types of problems: (1) The repetition of identical work under constant physiologic conditions for the study of training. (2) The repetition of identical work under variable physiologic conditions for the study of their effect on its cost. (3) The study of the physiologic effect of varying speed at a constant mechanical output. (4) The graphic record of fatigue curves. The advantages of the recording ergometer for repetitious work are obvious. The instrument lends itself especially well to studies necessitating variations in the speed of pedalling at constant output. A single manipulation, the alteration of the field current, accomplishes this since the rate of working remains constant as long as the load terminal voltage is unchanged.

#### SUMMARY

The electrodynamic brake principle has been applied to a stationary bicycle ergometer. It has furnished an easily adjustable brake with a constant coefficient of friction. The introduction of a recording voltmeter has made it possible to measure with accuracy the rate and steadiness of working. The

instrument may be used under a variety of speed and load conditions without the assistance of an operator.

The ergometer was built by J. S. Hipple, mechanician, in the shops of the Medical School. We wish to acknowledge his helpful suggestions and cooperative assistance in the development of this project.

## THE TRYPTOPHANE CONTENT OF BLOOD SERUM\*

---

### A NEW TECHNIC

---

ARTHUR T. BRICE, JR., B.A., M.T., PALO ALTO, CALIF.

---

MITCHEL and Hamilton<sup>1</sup> in their work on the amino acids quote J. M. Looney, as follows: "The multiplicity of the methods proposed for the estimation of tryptophane and the inconsistency of the values given are sufficient evidence of the importance attached to the subject and the worthlessness of most of the methods." Such a situation offers little encouragement to present another tryptophane method, but it does suggest that conflicting results in differentiating between normal and pathologic material might be avoided by some standardization of procedure. The tryosine content of the plasma proteins has been shown to be constant, and the determination of this amino acid can, therefore, be used as a measure of the total protein. Tryptophane, however, in the light of our present knowledge occupies a position more characteristic of an independent variable. Glycocol, alanine, serine, cysteine, aspartic acid, and glutamic acid are among the glucose formers of the amino acids. Valeine, leucine, isoleucine, phenylalanine and tyrosine give rise to beta-hydroxybutyric acid. Histidine and tryptophane are exceptions. It has been shown that tryptophane forms neither glucose nor beta-hydroxybutric acid in the organism of the dog. The tryptophane content of the plasma proteins has not been accurately established, and the practical application of a blood serum tryptophane method does not, therefore, at the moment seem apparent. The lack of such a present application, however, should not deter us from keeping our faculties of observation alive and seeking to learn what we can of physiologic or pathologic significance about this unique amino acid. It is with the hope that it may be used for such a purpose that the following technic for blood serum tryptophane is suggested.

---

\*From the U. S. Veterans' Administration Hospital, Palo Alto, California.  
Received for publication, September 27, 1933.

The specificity of the Adamciewicz reaction for tryptophane is entirely beyond question, and as applied in the Hopkins and Cole Glyoxylic test it has been shown to be quantitative within wide limits. It is particularly suitable for clinical laboratory application, as it is simple and rapid. I have developed its application to human blood serum and prepared an artificial color standard which is practically permanent if handled with ordinary care. The use of such a standard is open to criticism from the standpoint of absolute values, but aside from its comparatively negligible expense it has a distinct advantage over the chemical standard, which is notably unstable as a means for the accumulation of data. The chemical standard being subject to deterioration an element of error would likely creep into any series for which it might be employed, whereas with the artificial standard, assurance is had that the basis of comparison will not change throughout the series.

#### STANDARD

The standard is prepared from stock 0.05 per cent aqueous solutions preserved with a crystal of thymol of the DuPont water soluble dyes violamine blue and pontamine fast blue. Exactly 2.8 c.c. of each of these two stock solutions is diluted to 100 c.c. with a solution consisting of 3 per cent gelatin, 0.9 per cent sodium chloride, 5 per cent oxalic acid, and several crystals of thymol dissolved by heating on a boiling water-bath, cooling, and clearing by sedimentation, centrifugation, or filtration. A good grade of gelatin must be used and the diluting solution come through crystal clear with a trace of amber color. The DuPont dyes, which were developed specifically for use as color standards, are of absolutely uniform color value. They are light fast over a period of years if the solutions are kept in dark bottles. The gelatin vehicle is used to provide in the standard a molecular density, approximating that of the unknown blood serum mixtures. This standard may be prepared in the laboratory or may be purchased ready for use from the Hynson, Westcott and Dunning Company of Baltimore, Md., to which firm I am indebted for acquainting me with the properties and use of the DuPont water soluble dyes.

#### REAGENTS

*Hopkins-Cole Glyoxylic Reagent.*—To one liter of a saturated solution of oxalic acid add 60 gm. of 2 per cent sodium amalgam and allow the mixture to stand until the evolution of gas ceases. Filter and dilute with 2 or 3 volumes of water.

The glyoxylic reagent prepared according to Benedict's formula gives practically identical values with the above, but I have found it not to keep as well and old reagents to give less brilliance of color.

*Sulphuric Acid 95 per cent.*—A chemically pure or reagent quality of concentrated acid must be used, the usual U. S. P. grades giving cloudy solutions.

#### TECHNIC

a. Clear blood serum is diluted 1/10 with distilled water and 1 c.c., equivalent to 0.1 c.c. of serum, placed in a clean glass test tube.

b. Add 1 c.c. of glyoxylic reagent and then 3 c.c. of sulphuric acid, a few drops at a time, while shaking the tube.

c. Let stand for several minutes for the maximum color to develop and the mixture to cool somewhat and then compare in the colorimeter with the standard set at 15 or 20.

$$\text{Calculation: } \frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 100 = \frac{\text{mg. of total tryptophane per}}{\text{cent of blood serum}}$$

The standard will be found to be slightly more brilliant photometrically than most of the blood specimens but to provide a satisfactory basis for comparisons. The unknown solutions being strongly acid and quite hot must be handled carefully.

## A COMBINATION CONDENSING AND RECEIVING VESSEL\*

ROBERT A. GREENE, PH.D., AND RICHARD R. ROEHM, M.A., TUCSON, ARIZ.

DURING the past few months the authors have had occasion to make a number of protein analyses. Since only small amounts of material were available, Cavett's<sup>1</sup> micromodification of the Van Slyke method was used. In the determination of arginine, an aliquot of the basic fraction is hydrolyzed with strong NaOH, which converts arginine into ornithin and urea. After hydrolysis, ammonia is distilled into standard acid. In the original method of Holm<sup>2</sup> the ammonia is distilled through a condenser, but in Cavett's modifica-

Fig. 1.

tion, it is distilled into a receiving tube containing standard acid. A large test tube is usually employed as a receiver and must always be placed in a beaker of ice in order for it to function as a condenser. Although this method gives satisfactory results, it is not convenient, and necessitates a supply of ice. Consequently, a combined condensing and receiving vessel was constructed which functions better and which uses circulating water as the cooling agent. The construction of the vessel is shown in Fig. 1.

The condenser shell was constructed from glass tubing 5 cm. in diameter and 22 cm. in length. A water inlet was placed at the bottom of the tube and

\*From the Department of Agricultural Chemistry, University of Arizona.  
Received for publication, October 14, 1933.

an outlet was placed 4 cm. from the top of the tube. The receiving vessel was a pyrex test tube 3 cm. in diameter and 20 cm. in length. A rubber stopper (size No. 9) was bored to receive the test tube.

The standard acid is placed in the tube and the distillation conducted in the usual way. A current of tap water cools the test tube, which serves as a condenser. When the distillation is complete, the test tube may be removed and the solution titrated.

The authors have secured satisfactory results with this apparatus. It has been used for the determination of arginine in protein hydrolysates, and in the microdetermination of ammonia in biologic fluids and in bacterial cultures. It could also be used in micro-Kjeldahl determinations, eliminating a special condenser.

#### DOG-OPERATING TABLE\*

---

REGINALD A. CUTTING, M.D., C.M., M.A., Ph.D., NEW ORLEANS, LA.

---

SEVERAL months ago I was confronted with the task of outfitting a laboratory for dog surgery. A definite problem was encountered in connection with securing suitable dog-operating tables. After some preliminary experimentation with the various types of tables with which I was familiar, all of which proved to present disadvantages, it was decided to attempt to design a more satisfactory type of apparatus. The design of the dog-operating table which was finally developed and which experience at the Louisiana State University Medical Center has shown to be particularly useful and convenient, is herewith submitted in the belief that it embodies features which may be of interest to others working in the educational and laboratory fields.

The characteristics which were stressed in designing the table were: (1) So far as possible, an all metal construction; (2) portability, such that the table could be readily handled by one person; (3) quick and easy disassembly of the entire apparatus; (4) absence of all pockets and depressions in which dirt might accumulate; (5) accessibility of all parts for easy cleaning with soap and water; (6) a wide range of utility; and (7) sturdiness and stability.

The table is constructed of pipe iron, angle iron, and monel metal, the only wood used in its construction being two monel metal covered boards which constitute a troughlike support for the animal's body.

\*From the Department of Surgery, Louisiana State University Medical Center, and the Charity Hospital.  
Received for publication, August 28, 1933.

*Dimensions:* Fig. 1 shows the completely assembled table. The over-all dimensions of this table, exclusive of the instrument tray (which is removable) are as follows: height 40 inches, length 47 inches, width  $16\frac{1}{2}$  inches. Fig. 2 is a photograph of the bare frame of the table. For the most part this frame consists of pipe iron, of 1 inch diameter, outside measure, the pieces being cut to length and solidly welded together. The over-all dimensions of the frame of the table (exclusive of the instrument tray) are: height  $36\frac{1}{2}$  inches, length

Fig. 1.

Fig. 2.

46 inches, width 16 inches. The extreme top of the frame is made of angle iron which measures  $1\frac{1}{4}$  inches on a side. The angle iron portion of the frame is open at the extreme right end, for the insertion of a monel metal pan, subsequently to be described, which slides in and out on the lower surface of the angle iron, like a drawer. The cross braces of pipe iron at the bottom of the table are ten inches on center from the floor. The end cross braces of pipe iron at the top of the table are respectively  $25\frac{1}{2}$  inches (right end of the table),

and  $31\frac{1}{2}$  inches (left end of the table), on center from the floor. The side braces of pipe iron at the top of the table are  $32\frac{1}{2}$  inches on center from the floor. At the right end of the table, above the cross braces nearest the floor, there is an arrangement made of strap steel, for the reception of a white enamel ware bucket. This consists of a ring suitably braced both to the legs of the table, and also to the base on which the enamel ware bucket rests. The base for the bucket is provided by two cross pieces of strap steel, welded to the lower cross braces of the table. The steel used in this part of the construction is 1 inch wide, and  $\frac{1}{8}$  inch thick. All joints are firmly welded.

The instrument tray measures  $17\frac{1}{2}$  by 13 inches. The frame of the tray consists of angle iron, welded at the corners in the form of a rectangle. The angle iron measures one inch on a side. Two cross braces of strap steel are welded across the bottom of the frame of the tray, and flush with its lower surface. They measure 1 inch in width and  $\frac{3}{16}$  inch in thickness. The tray

Fig. 3.

is supported by a right-angled steel rod. The horizontal limb of this rod measures 7 inches in length, and is welded both to the midportion of one end of the angle iron frame of the tray, and also to the midportion of the proximal strap-steel crossbar. The vertical limb of the rod measures 22 inches in length and  $\frac{9}{16}$  of an inch in diameter. The vertical limb of the rod provides support for the instrument tray in the following manner: A tubular piece of pipe iron, 6 inches in length is welded to one leg of the table by the intermediation of two offset pieces of strap steel, 1 inch in length and  $\frac{3}{16}$  of an inch in thickness. Through this piece of pipe iron, the vertical rod of the instrument tray passes in a snug fit. The tray is made adjustable for height by means of a collar and set screw, the position of which can be varied at will. The distance between the floor and the lowermost extremity of the offset pipe iron support for the instrument tray, is 26 inches. The instrument tray is not only adjustable for height, but swings freely on its supporting rod through an angle of 360 degrees.

Fig. 3 shows the frame of the table together with the accessory parts. These consist of (1) a monel metal instrument tray which fits inside of the instrument tray frame previously described, (2) a sheet monel metal drip pan, which slides in the groove provided by the angle iron top of the table, (3) a monel metal cabinet for the reception of ether cans, masks and other incidental paraphernalia connected with the anesthetization of the animal, and (4) a monel metal, wood, and strap-iron top constructed in a V-shape on which the animal lies.

The instrument tray pan is made to fit snugly into the angle iron tray frame, previously described. It measures slightly less than 17 inches in length, and slightly less than 13 inches in width, and is one inch deep. The edges are neatly turned over a heavy wire frame. The tray is neatly soldered so that it does not leak.

The drip pan is constructed of monel metal, and is of such dimensions that it provides a good sliding fit for the angle iron top of the table. Two flanges,  $\frac{7}{8}$  of an inch in width are provided on the edges at the top of the pan, one projecting from either side, on which the pan slides. The pan is  $1\frac{1}{2}$  inches deep at its shallower end, and 6 inches deep at its deepest part. The bottom of the pan slopes considerably at both ends, and also slightly on both sides. At the center of the extreme lower edge of the pan is soldered a drain spout which is  $2\frac{1}{2}$  inches in length, and  $\frac{3}{4}$  of an inch in diameter. This extreme lower edge of the pan is  $6\frac{1}{2}$  inches from the end of the table, and the drain spout centers accurately over the receptacle for the enamel ware bucket—or over the bucket itself when the bucket is in place. The upper edge of this drip pan is turned neatly over a heavy wire frame. The pan is neatly soldered so that it does not leak, and inasmuch as its sides slope in all directions, it drains very efficiently.

The cabinet for anesthetic paraphernalia is made of monel metal. It is  $12\frac{1}{2}$  inches wide, and 9 inches from front to back. The back of the cabinet is 18 inches in height. The sides of the cabinet at the top slope toward the front which is  $9\frac{1}{2}$  inches in height. The edges of the top of the cabinet are neatly turned over a heavy wire frame. The front of the cabinet projects for a distance of  $1\frac{1}{4}$  inches in the form of a flange at the sides, the dimensions of the front of the cabinet being  $14\frac{1}{2}$  inches in length, and  $9\frac{1}{2}$  inches in height. The flanges fit against the legs of the table, and prevent the cabinet from being displaced backward or inward. Riveted to the back of these projecting flanges, are a pair of strap metal hooks, one placed above the other, and one pair on either end. These hooks engage studs which project inward from the legs of the table, and prevent the cabinet from being accidentally displaced forward or outward. The cabinet is easily removable, however, by raising it straight up, thus disengaging the hooks from the studs. The cabinet rests on the cross supports of pipe iron at the bottom of the table. It is neatly soldered, so that it will not leak.

The top of the table on which the animal rests consists of a V-shaped trough, fashioned from two monel metal covered wooden boards. These boards measure 8 inches wide,  $47\frac{1}{2}$  inches long, and  $\frac{7}{8}$  of an inch in thickness.

As previously mentioned, the two boards form a trough, being separated throughout by a distance of  $1\frac{1}{2}$  inches. Four similar supports of angle iron bolted at regular intervals to the bottoms of the monel covered boards maintain the angle of the trough, and support this trough on the extreme edges of the top of the table frame. These angle iron supports are made of 1 by  $\frac{3}{16}$  inch cold rolled steel stock, bent on a template. They consist of a horizontal bar to which is welded at three places an inverted W-shaped piece of steel. The table top rests on the extreme upper edge of the angle iron frame of the table proper. The nature of the construction prevents displacement of the top of the table from side to side. Metal stops welded to the extreme end of the frame of the table proper, at its open end, prevent the top of the table from becoming displaced in that direction. The top of the table is, however, readily lifted, vertically.

All iron and steel parts of the table are finished with several coats of white enamel.

In operation, the table is extremely satisfactory. Not only is it pleasing to the eye, but all parts are easily removed without necessarily disturbing any other part of the table. The anesthetist's cabinet is disengaged by simply lifting it, and it can be emptied and cleaned with soap and water. The drip pan slides freely from the end of the table without disturbing the trough on which the dog lies. This pan is made entirely of rustless metal, and can be scrubbed into a condition of perfect cleanliness with soap and water. The instrument tray and instrument tray frame can be disassembled by a simple lifting movement. Similarly, the white enamel bucket, although it is entirely stable in its ring stand, can be readily lifted from its position and thoroughly cleaned. The top of the table, consisting of the trough in which the animal lies, although it is thoroughly stable, with respect to end and sidewise motion, can be readily lifted vertically, together with the animal if desired, without disturbing the rest of the ensemble.

NOTE.—This table was skillfully constructed jointly by the pipe-fitting, sheet metal working, carpenter, and paint shops of the Charity Hospital of New Orleans to my plans and specifications, and I am indebted to the mechanics for certain constructional modifications of the original design. The cost of the completely finished tables was \$39.60 apiece.

## ESTIMATION OF PLASMA BILIRUBIN<sup>2</sup>

### A COMPARATIVE STUDY OF THE VAN DEN BERGH AND THE THANNHAUSER AND ANDERSEN PROCEDURES

E. H. BENSLEY, MONTREAL, CANADA

THE purpose of this communication is to record a series of quantitative determinations of plasma bilirubin by the van den Bergh and the Thannhauser and Andersen techniques, and to compare the two methods *with respect to their applicability in clinical work*.

Van den Bergh<sup>1, 2, 3</sup> noted that with his procedure the protein precipitate, formed by the addition of alcohol to serum, may, at times, carry with it considerable amounts of bilirubin and, as a consequence, values obtained for serum bilirubin may be low. Such loss of bilirubin, however, did not occur or was negligible when sera contained no "direct" bilirubin. Thannhauser and Andersen<sup>4</sup> attempted to eliminate this source of error by coupling the bilirubin with the diazo reagent before precipitation of proteins with alcohol. Thus, according to the van den Bergh technic,<sup>2</sup> the serum (or plasma) proteins are first precipitated with alcohol and the protein-free portion is treated with the diazo reagent; whereas, with the Thannhauser and Andersen procedure<sup>4</sup> the diazo reagent is added to the serum (or plasma) *before* precipitation of the proteins. Thannhauser and Andersen also suggested the addition of ammonium sulphate to ensure complete precipitation of protein. Comparison of the values obtained by these two methods<sup>4, 6, 7, 8, 9</sup> indicates that loss of bilirubin by occlusion in the protein precipitate is considerably reduced by the Thannhauser and Andersen technic.

In this Clinic, the van den Bergh method has been used since 1922. Over five thousand determinations have been made, and correlation between plasma bilirubin values and clinical findings has been satisfactory, with one exception; in cases of subsiding jaundice, there appears to be no relationship between the color of the skin and the amount of bilirubin in the blood. This absence of relationship was thought to be due to the rate at which bilirubin is liberated from the tissues in this condition; at times, liberation of bilirubin from the tissues may be slow and the rate at which the pigment enters the blood may be much lower than the rate at which it can be removed. This would explain the frequent finding, in such cases, of jaundice of the skin in spite of normal or nearly normal amounts of bilirubin in the blood. In view of the definitely established fact that the van den Bergh procedure may not be quantitative when the blood contains "direct" bilirubin, it is necessary to seek an explanation of the generally satisfactory results with this technic in

<sup>2</sup>From the Department of Metabolism, The Montreal General Hospital.  
Received for publication, October 16, 1933.

this Clinic. I was, therefore, prompted to compare the van den Bergh procedure with that of Thannhauser and Andersen and correlate the data with clinical findings.

#### METHODS

Oxalated plasma was used and all tests were commenced within one hour of collection of blood. Van den Bergh's cobalt-sulphate standard was used.<sup>6</sup> All determinations were carried out by the writer.

*Van den Bergh Technic.*—Two volumes of 95 per cent alcohol were well mixed with one volume of plasma and the mixture was centrifuged. To 1 c.c. of the clear supernatant fluid was added 0.5 c.c. of 95 per cent alcohol and 0.25 c.c. of freshly prepared diazo reagent. Fifteen minutes were allowed for full color development. The solution was then diluted with 66 per cent alcohol until the color matched that of the standard. In estimating the bilirubin, a dilution factor of 1 in 5 was used.<sup>10</sup>

*Thannhauser and Andersen Technic.*—There was 0.5 c.c. of freshly prepared diazo reagent mixed with 1 c.c. of plasma, and fifteen minutes allowed for full color development. There were 2.5 c.c. of 95 per cent alcohol and 1 c.c. of saturated aqueous solution of ammonium sulphate then added. After thorough mixing and centrifuging, a portion of the supernatant fluid was removed and diluted with 33 per cent alcohol until the color matched that of the standard. In estimating the bilirubin, a dilution factor of 1 in 4 was used.\*

#### DISCUSSION OF RESULTS

There is fairly general agreement that loss of bilirubin due to occlusion in the protein precipitate does not occur or is negligible when there is no "direct" bilirubin in the blood. In such cases, there are no significant differences between values obtained by the two methods. In this investigation, therefore, only plasmas containing "direct" bilirubin were used. All showed a "biphasic" direct reaction. In all, one hundred determinations were made in forty-three cases. The plasma bilirubin ranged between 0.3 and 32.0 units. Losses of bilirubin with the van den Bergh technic were calculated from the differences between values obtained by the two methods, it being assumed that no loss occurred with the Thannhauser and Andersen technic. The combined results are shown in Table I.

TABLE I  
SHOWING LOSS OF BILIRUBIN WITH THE VAN DEN BERGH METHOD

|                                      | BILIRUBIN<br>RANGE<br>(UNITS) | NUMBER<br>OF<br>TESTS | PERCENTAGE LOSS |     |       |       |       |
|--------------------------------------|-------------------------------|-----------------------|-----------------|-----|-------|-------|-------|
|                                      |                               |                       | NONE            | -20 | 21-40 | 41-60 | 61-80 |
| Combined data                        | 0.3-32.0                      | 100                   | 44              | 21  | 14    | 16    | 5     |
|                                      | - 4.0                         | 66                    | 40              | 8   | 4     | 10    | 4     |
|                                      | 4.1-32.0                      | 34                    | 4               | 13  | 10    | 6     | 1     |
| Subsiding jaundice                   | 1.0-13.2                      | 27                    | 0               | 1   | 5     | 16    | 5     |
| All cases, except subsiding jaundice | 0.3-32.0                      | 73                    | 44              | 20  | 9     | 0     | 0     |
|                                      | - 4.0                         | 51                    | 39              | 9   | 3     | 0     | 0     |
|                                      | 4.1-32.0                      | 22                    | 5               | 11  | 6     | 0     | 0     |

It will be observed that, with the van den Bergh technic, losses of bilirubin ranged between zero and over 60 per cent. When the data are grouped

\*In 65 of the 100 determinations, the protein precipitate and supernatant fluid as rubin values obtained by the assumed (1:1) the significance of the results.

calculated from the volume of The differences between bili- estimated factors were not sufficient to affect

according to concentration of bilirubin, it would appear that, in general, the higher the concentration the greater the loss. Losses ranging from zero to over 60 per cent were, however, still noted regardless of concentration. In view of the observation that the van den Bergh method was found unsatisfactory in cases of subsiding jaundice, it is of interest to note that the greatest losses occurred in this type of case; of 27 such determinations, losses exceeded 40 per cent in 21. In all other cases, the loss of bilirubin with the van den Bergh technic was relatively small; though losses were greater with plasmas of high, than with those of low, bilirubin content, they never exceeded 40 per cent and, in most, were less than 20 per cent regardless of concentration. That the marked losses of bilirubin noted in the cases of subsiding jaundice were not accidental is shown by repeated determinations in the same individual (Tables II, III, and IV).

| 11.0                        | 13.2                                     | 17                                                                 | Jaundice commencing to fade  |
| 4.7                         | 8.8                                      | 47                                                                 | Jaundice rapidly subsiding   |
| 4.0                         | 9.2                                      | 56                                                                 |                              |
| 1.3                         | 4.8                                      | 73                                                                 | Still slight jaundice        |

The observation that the van den Bergh technic is not even approximately quantitative in subsiding jaundice explains largely the absence of relationship noted at times between the clinical picture (color of the skin) and the bilirubin content of the blood in this type of case. With the Thannhauser and Andersen technic the discrepancy is not nearly so marked, although there is still evidence that, at times, the rate at which bilirubin enters the blood from the tissues is lower than the rate at which it can be removed. In all other types of cases investigated, the van den Bergh technic, although not strictly quantitative, is sufficiently so for clinical purposes. It may here be noted that it was found that in the detection of "latent" jaundice, both technics are equally sensitive.

#### SUMMARY

One hundred determinations were made of the bilirubin content of blood by the van den Bergh and the Thannhauser and Andersen methods in cases with "direct" bilirubin. Both methods were used in each case and determinations were made simultaneously.

In subsiding jaundice, the values obtained by the van den Bergh technic are not even approximately correct; loss of bilirubin may be as much as 60 per cent or more. In such cases, therefore, the Thannhauser and Andersen procedure is indispensable. In all other cases, however, including latent jaundice, the van den Bergh technic, although not strictly quantitative, is sufficiently so for clinical purposes.

## A METHOD OF PREPARING DUODENAL POUCHES FOR USE IN EXPERIMENTAL WORK\*

---

FREDERICK C. HILL, M.D., IRWIN NEIGUS, M.S., AND  
CHARLES M. WILHELMJ, M.D., OMAHA, NEB.

---

DURING the course of experimental investigations of the secretions found in the duodenum, it sometimes becomes desirable to prepare an isolated segment of the duodenum, one end of which opens on the abdominal wall. By means of such a pouch studies may conveniently be made of the duodenal contents, uncontaminated by juices from the stomach or jejunum. If the openings of the bile and pancreatic ducts are included in the segment of duodenum utilized for the pouch, as is usually the case, certain difficulties present themselves. As Elman and McCaughan<sup>1</sup> have shown, the duration of life after a fistula of the pancreatic ducts has been established is a matter of only a few days, and the animal will thus not live long enough to permit firm healing of the closed end of the pouch. During the first week there is apt to be an inflammatory reaction at the suture line which might interfere with normal experimental results, and in addition if fluid is introduced into the pouch under any degree of pressure there may be leakage at the suture line. We have had occasion to prepare and use a number of duodenal pouches,<sup>2</sup> and have found that the above factors are eliminated if the pouch is made by the following method:

Under intratracheal ether anesthesia, and using aseptic technic, the abdomen is opened through a midline incision extending from the ensiform cartilage downward about 4 inches. (We have used the dog in all of our work.) The first part of the jejunum is identified and marked by an Allis forcep. The pyloric end of the stomach and the first portion of the duodenum are brought up, packed off, and severed between heavy clamps at the pylorus. The end of the stomach and the adjacent end of the duodenum are then inverted and closed by two layers of 00 chromic catgut. The previously marked jejunum is then approximated to the anterior surface of the stomach and a gastroenterostomy is performed. The abdomen is closed in the usual manner. This constitutes the first stage of the operation, and the animal is now allowed a period of recuperation, usually about two weeks, before the second procedure. During this time

---

Received for publication, October 16, 1933.

the closed end of the duodenum, which will be the blind end of the pouch, has an opportunity to heal completely, and the animal returns to a normal physical condition.

The second stage of the operation requires only a few minutes and is performed as follows: The abdomen is again opened through a part of the length

Fig. 1.—The first stage in the preparation of a duodenal pouch. The duodenum has been severed from the stomach at the pylorus, the open ends have been closed, and an anterior gastroenterostomy has been performed.

Fig. 2.—At the conclusion of the second stage of the operation: the duodenum has been cut off almost 6 inches from the pylorus and the open end has been brought through the abdominal wall. The distal duodenal stump has been closed.

of the original incision, and the duodenum is brought up into the wound. The field is packed off, and crushing clamps are placed on the duodenum about six inches from the closed end. The duodenum is severed between the clamps, and the stump nearest the jejunum is inverted and closed by two layers of

00 catgut or fine silk. A stab wound is made through the right rectus muscle near the costal margin, an Allis forcep is inserted into the abdomen through the stab wound, the crushing clamp is removed and that end of the duodenum is grasped and drawn out. The agglutination of tissues produced by the heavy clamp keeps the end of the duodenum closed while it is being drawn out, and there should be no soiling by duodenal juices. The open end of the duodenum is anchored to the peritoneum, fascia, and skin, care being taken not to interfere with the blood supply. The abdominal wound is closed again by the usual method. There is usually some shrinkage of the pouch, but we have found that if it is originally made 6 inches long, it will remain satisfactory. Most of our pouches held about 30 c.c. The pouch, when completed, retains its original nerve supply and the blood supply is, of course, very carefully preserved.

Fig. 3.—Photograph of the dog's abdomen showing the stoma of the pouch with the catheter and rubber stopper in place. Fluid is being withdrawn from the pouch by means of a syringe.

Owing to the extreme rapidity with which the physical condition of the animal deteriorates as soon as the bile and pancreatic juices begin to drain to the outside, it is advisable to start the proposed investigations within a short period of time. We are accustomed to begin the first series of experiments within eighteen hours after the completion of the operation. In order to keep the animal in good physical condition as long as possible, daily injections of 500 to 1,000 c.c. of 2 per cent sodium bicarbonate in normal saline solution should be given daily. We have found that fluid given subcutaneously in the dog is absorbed rapidly and can be given with ease and in large amounts. If the animal is in a debilitated condition, it is frequently difficult and time consuming to give fluid intravenously each day, and the subcutaneous route has given perfect satisfaction.

In a pouch prepared by the above method, with the duodenum brought out through the rectus muscle, there would in time be some valve action developed

at the stoma as the mucosa shrinks down. When the pouch is used early, however, and the mucosa still protrudes some distance from the wound, we have found it necessary in most cases to use a mechanical method of insuring that there will be no loss of fluid during an experiment. A rubber catheter, size 16 French, is passed through a rubber stopper of such size as to occlude the opening of the pouch. The catheter and stopper are adjusted so that when the stopper is in place in the stoma the catheter will project about 2 inches into the pouch. By means of a syringe, fluid may now be introduced into or withdrawn from the pouch without any leakage, especially if the stopper is held in place by manual pressure. In some cases it may be found that there is oozing of blood from the protruding mucosa in the earlier experiments, before any healing has taken place. If this might invalidate the experimental data, the bleeding may be easily stopped by touching the hemorrhagic edges with the cautery.

## RETICULOCYTES\*

EDWIN E. OSGOOD, M.D., AND MABLE M. WILHELM, A.B., PORTLAND, ORE.

RETICULOCYTES are young red cells, and therefore, a reticulocyte count gives the best evidence of the state of activity of the bone marrow. It is indicated in the study of any anemia and is especially important if pernicious anemia, aplastic anemia, or familial hemolytic icterus is being considered. An increase in the reticulocytes is the first indication of a favorable effect from therapy in anemias, whether that therapy be liver, iron, or any erythropoietic stimulant. Since the reticulocyte count is so important and is so frequently done, it is desirable to have a simple and accurate method which will give uniform results. It is evident from the large number of methods in use and from the wide variation (from as low as 0 to 0.1 per cent<sup>1</sup> to as high as 1.0 to 3.0 per cent<sup>2</sup>) in values given for normals, that a uniformly satisfactory method has not yet been devised.

While attempting to find the most desirable method of those now in use, a technic was worked out which seemed even more simple and showed more reticulocytes in a particular blood than any other method tested. It has the

\*From the Departments of Medicine and Biochemistry and the Clinical Laboratory of the University of Oregon Medical School.

Read before the Oregon State Medical Society, Eugene, Oregon, October 22, 1931.

additional advantage of being adapted for use with oxalated venous blood in our uniform system<sup>3</sup> of hematologic methods. Evidence was further adduced to show that the reticulocyte stain is not a vital stain, as is usually stated, but will stain dead cells, if they are not fixed.

#### STUDY OF METHODS

Methods for reticulocyte staining may be classified in the following groups:

1. Methods in which the dye is dried on the cover slip or slide.
  - (a) Moist cover slip preparations.
  - (b) Dried smears.
2. Methods in which the blood is mixed with a solution of the dye.
  - (a) On the slide or cover slip.
  - (b) In test tube, pipette, watch glass, etc.

Obviously, the concentration, time of exposure to, and nature of the dye used may be varied with each one of these fundamental technics. Various dyes have been tried, but brilliant cresyl blue has been found so superior that the others need not be considered.

A series of experiments were performed to decide which of the above fundamental technics was most satisfactory. The methods were selected from the current literature and the textbooks in common use.

Blood was drawn from the vein of a patient with pernicious anemia and used for Methods A to F below and the remainder mixed with 2 mg. of potassium oxalate per cubic centimeter of blood and used for our experiments with oxalated blood. Five hundred red cells were counted in each experiment.

Method A: A small drop of fresh blood was placed on a cover slip, ringed with vaseline to prevent drying, and inverted onto a slide which had been smeared with a drop of saturated alcoholic solution of brilliant cresyl blue and allowed to dry. These were examined after thirty minutes. Some reticulocytes could be seen, but the smears were too thick and the red cells too unevenly distributed for accurate counting.

Method B: Smears of fresh blood were made on slides which had been smeared with a drop of saturated alcoholic solution of brilliant cresyl blue and allowed to dry. These smears gave a count of 7.6 per cent reticulocytes, which seemed to be well stained.

Method C: One drop of fresh blood was added to one drop of stain on a slide, mixed and smeared. The stain was made by mixing 2 c.c. of 1 per cent aqueous brilliant cresyl blue and 8 c.c. of 0.2 per cent potassium oxalate in 0.6 per cent sodium chloride solution, giving a final concentration of 0.2 per cent brilliant cresyl blue, 0.18 per cent potassium oxalate and 0.48 per cent sodium chloride. These smears gave a count of 8.2 per cent reticulocytes, which seemed to be well stained.

Method D: Fresh blood was drawn up to the 1 mark in a white cell pipette and filled with stain to the 11 mark and mixed thoroughly. After standing fifteen minutes, the pipette was shaken for two minutes and smears made, drying above a flame. The stain was made by mixing 3 parts of a 0.3 per cent solution of brilliant cresyl blue in 0.85 per cent sodium chloride and 1 part 0.3 per cent sodium citrate in 0.6 per cent sodium chloride, giving a final concentration of 0.075 per cent brilliant cresyl blue, 0.075 per cent sodium citrate, and 0.66 per cent sodium chloride. An occasional reticulocyte was seen, but the cells on these smears were crenated, making accurate counting impossible.

Method E: One drop of fresh blood was added to 20 drops of stain (prepared as in Method C) in a centrifuge tube, let stand for twenty minutes and centrifugated. Smears were

made of the sediment, drying over a flame. These smears gave a count of 9.6 per cent reticulocytes, which seemed to be well stained. The red cells were crenated in several of these smears.

Method F: Two drops of fresh blood were added to 25 drops of stain in a centrifuge tube, allowed to stand for twenty minutes, and then centrifugated. The stain was prepared by mixing 1 part of 1 per cent brilliant cresyl blue in 0.85 per cent sodium chloride and

TABLE I

| METHOD | RETICULOCYTES     |
|--------|-------------------|
| A      | Poor distribution |
| B      | 7.6%              |
| C      | 8.2%              |
| D      | Crenated          |
| E      | 9.6%              |
| F      | 17.6%             |
| G      | 23.6%             |

5 parts of 1.0 per cent potassium oxalate in 0.85 per cent sodium chloride, giving a final concentration of 0.17 per cent brilliant cresyl blue, 0.17 per cent potassium oxalate, and 0.85 per cent sodium chloride. Smears were made of the sediment, drying over a flame. These smears gave a count of 17.6 per cent reticulocytes, which seemed to be well stained. There was a tendency toward crenation of the cells.

From these experiments, it was concluded that the fundamental Method 2(b) is much the most satisfactory because it permits more accurate control of the concentration of dye with which the cells come in contact and of the time of exposure of the cells to the dye, and because the technic is simple and gives permanent preparations if counterstained with Wright's stain. The wide variation in counts on the same blood specimen by the different methods (Table I) proved that accurate control of these factors is necessary, and that most, if not all, of these methods fail to demonstrate all the reticulocytes actually present.

Further experiments were planned to find out whether oxalated blood could be used and to determine the optimum concentration of dye and time of exposure. Using Method F, which gave the highest count with the fresh blood (17.6 per cent) and the oxalated blood which had stood at room temperature for one hour, a count of 14.6 per cent reticulocytes was obtained, proving oxalated blood to be satisfactory. By using equal parts of oxalated blood and dye solution, satisfactory smears were obtained without centrifugation. Since the blood already contained an anticoagulant, the oxalate solution was omitted and mixing the blood with an equal volume of brilliant cresyl blue solution in 0.85 per cent sodium chloride was tried. Using a series of dye concentrations from 0.075 per cent to 14.0 per cent (saturated), it was found that a 1.0 per cent solution gave the maximum number (23.6 per cent) of reticulocytes with the minimum amount of debris on the slide. Concentrations below 1.0 or over 3.0 per cent gave low counts; the concentrations above 1.0 up to 3.0 per cent gave quite satisfactory smears when counterstained with Wright's stain. Using equal parts of the 1.0 per cent dye solution and oxalated blood, the time of exposure to the dye was varied from mixing on the slide (fifteen seconds)

to twenty-four hours, and it was found that results were satisfactory for all times over one minute, but that low counts were obtained if the time were thirty seconds or less. Red cell counts made on the original blood and on an accurate dilution with the dye solution showed that no hemolysis occurred.

From these experiments, it was concluded that the following is the most satisfactory technic for staining and counting reticulocytes: Mix, in a small test tube, equal parts (5 drops) of oxalated venous or capillary blood and 1 per cent of brilliant cresyl blue in 0.85 per cent sodium chloride solution. Let stand at least one minute, mix, and make thin smears, drying in the air as usual. These smears may be counted at any time within twenty-four hours, but if a permanent preparation is desired, they should be counterstained with Wright's stain by the usual technic. The brilliant cresyl blue solution keeps well but should be filtered if débris appears on the slide. Select an area on the slide which contains 50 to 75 red cells per oil immersion field. Count all the cells and all the reticulocytes in as many adjacent fields as is necessary to give a total of 500 red cells if the count is over 5 per cent, or 1,000 red cells if the count is less than 5 per cent reticulocytes. With this method, a count of 23.6 per cent was obtained in the blood which gave 17.6 per cent with the best method previously studied.

Using this technic (Method G) reticulocyte counts were made at intervals for twenty-four hours after drawing blood, and then at twenty-four-hour intervals up to ninety-six hours, and again at one hundred and forty-four hours. To our surprise, the counts showed no significant variations during the six days (Table II), although after ninety-six hours the blood was badly hemo-

TABLE II

| TIME AFTER DRAWING<br>BLOOD | RETICULOCYTES<br>PER CENT |

lyzed. This showed that oxalated venous blood could be safely used for at least twenty-four hours, and suggested to us that this was not a vital stain, if the term "vital stain" is used in its strictest sense of a stain which acts only on living cells and in staining causes cell death. To aid in deciding this point, equal parts of oxalated blood and 1 per cent sodium cyanide were mixed and reticulocyte counts were done at intervals up to three hours. No significant variations in the reticulocyte counts from those on the untreated blood were found. Another sample of oxalated blood was mixed and divided into two parts. To one part sodium fluoride was added in the proportion of 10 mg. per c.c. Reticulocyte counts were made at intervals for twenty-four hours on both samples with the results shown in Table III. When the red cells were fixed by methyl or ethyl alcohol, formalin, or flame, the reticulocytes did not stain. The results of these experiments support the opinion<sup>4</sup> that the reticulum can be stained in unfixed, but not necessarily living, red cells.

#### NORMAL VALUES

To determine normal values for the improved technic, reticulocyte and red cell counts were done on 110 healthy young men and 50 healthy young women, with the results shown in Table IV. Note that the average figure is 1.57 per cent and the range from 0.5 to 3.8 per cent for both men and women. The total number of reticulocytes calculated from the red cell count averages 83,160 per c.mm. for men and 72,800 per c.mm. for women and shows a range of from

26,050 to 211,660 and from 21,400 to 156,800, respectively. Studies of normal hematology of over 200 children of school age show practically the same percentage values for reticulocytes. For clinical purposes, the average normal may be regarded as 1.5 per cent with figures below 0.5 or above 4.0 per cent, indicating decreased or increased red cell formation, respectively. Observe that these figures are significantly higher than those generally given and that reticulocytes were found in all normal bloods.

#### SUMMARY

A study of the methods for reticulocyte staining in common use showed a great number of different technics giving widely variant results.

A simple technic was worked out which gives uniformly good results and significantly higher counts than other methods tested.

Normal values for this method are 1.5 per cent with a range of 0.5 to 4.0 per cent. Since the percentage values for both sexes at all ages are the same, while the absolute counts differ markedly, it would seem better to report reticulocyte counts in percentage rather than in absolute numbers.

Evidence is presented which suggests that the term "vital" should not be used when referring to the reticulocyte stain.

#### SMALL ANIMAL METABOLISM CAGE\*

---

SEWARD E. OWEN, PH.D., HINES, ILL.

---

THE cage design presented here offers several advantages over the usual small animal cage. Among these advantages are (1) low cost per cage, the size given when completed averaging about forty cents each; (2) ease of construction, as no solder is necessary; (3) ease of cleaning; (4) immediate accessibility to the animals, which are visible at all times; (5) feed boxes and water founts which can be changed without opening or moving the cage; (6) the construction which

\*From the Cancer Research Unit, Veterans' Administration Facility.

Published with the permission of the Medical Director of the Veterans' Administration.

permits of separation of urine and feces for examination; (7) the convenience of weighing animals without removing them from the cage.

The construction requires no special tools other than a pair of heavy shears, or tin snips, and pliers. The cage proper is a cylinder of  $\frac{5}{8}$ -inch mesh galvanized screen with a fitted bottom of the same material. Covers are made from  $8\frac{1}{2}$ -in. tin pot covers; the bottoms are tin pie pans of the same dimension. These items can readily be obtained from the local stores.

The cage size as used in our laboratories for rats is 10 in. high and 8 in. in diameter with the floor placed about  $2\frac{1}{2}$  in. from the cylinder bottoms. This height prevents coprophagy in vitamin work.

The mesh is cut so as to leave protruding mesh ends which are bent to form an L. These are clinched over in forming the cylinder as shown in Fig. 2, I. The floor of the cage may be wired to the walls as at *x* (Fig. 1), or stiff cross-

Fig. 1.

wires such as made from baling wire may be placed across the inside of the cylinder for the bottom to rest on. This latter procedure may allow of easier cleaning although some rigidity is lost by it. If the floor is made removable as suggested, it should be bound with tin strips. Such strips can be wired to the floor plate easily by punching holes in the binding strip. The cover hinge as well as the snap and water-fount support are made from baling wire. The cover hinge is an overlapped ring of the wire placed as shown.

The food tunnel is shaped from material obtained from discarded tin cans. These pieces were made into boxes about 10 cm. long by 5 cm. square with one end closed and the edges of the open end flared to fit the slots attached to the cage at *A* (Fig. 1). Small aluminum rivets were used to hold the box rigid and to attach the top of an ointment jar. The ointment jars or food jars are of porcelain or glass 6.5 cm. in diameter and 6 cm. high. By cutting an opening through the bottom of the feed tunnel and the attached ointment jar top, the animal is allowed ready access to the food. Spillage and wastage is thus cut

down, and the food jar may easily be removed for weighing, cleaning, and filling. If desired, the food tunnel opening can be fitted with tin squares which have holes of various sizes according to the rat size. In other experiments not requiring the accurate checking of food consumption, the slot *A* holds a plain piece of sheet tin and the food jars may be placed inside the cage. For daily checking of food weights, a glass of food or seed jar such as is used on canary cages may be used; this makes a more compact assembly, but these jars do not hold sufficient food for several days' feeding.

The water founts are the usual inverted bottles with L-shaped glass tubes having an opening blown on the upper surface of the lower limb as sketched at *H* (Fig. 2).

Fig. 2.

When using the cages in which separate urine and feces samples were desired, six-inch holes were bored in the shelf supporting the cages. Seven-and-a-quarter-inch glass funnels were placed in these holes and the cages placed over the funnels. Screens made from No. 60 brass strainer net were placed in the funnels to collect feces while the urine drained into small tubes or flasks placed at the funnel tips on a lower shelf. The funnel tip may be narrowed to deliver drops and a continuous record of urine secretion obtained by the use of methods suggested by Owen.<sup>1</sup> While we have routinely filtered urines before extraction in studies of drug excretion (Owen and Olsen<sup>2</sup>), this is usually not essential unless a dry, finely divided food is used.

# DEPARTMENT OF REVIEWS AND ABSTRACTS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

**TUBERCULIN, Ointment Patch Test, Wolff, E.** *Am. J. Dis. Child.* 47: 764, 1934.

The author describes tests with an ointment composed of highly concentrated tuberculin and killed tubercle bacilli. The area of application is the paravertebral region between the eighth and eleventh thoracic vertebrae, or the medial brachial surface.

The skin is cleansed with green soap and water, dried gently, bathed with benzene, and then gently dried again. The application of benzene only, as heretofore practiced, is not sufficient to remove the secretions from very oily skins. A pea-sized drop of the tuberculin ointment is applied on the right side, and a similar sized drop of the control ointment is applied on the left side. Each of these drops is covered with a 2-inch (5 cm.) square of adhesive tape.

The test is read in forty-eight hours. The adhesive tape is removed after soaking with benzene, and the area is gently cleansed with benzene. The reaction may be clearly observed ten minutes after the removal of the tape.

Positive reactions exhibit papules, erythema, induration, and pigmentation. A weak positive test shows a few (not more than twenty) discrete papules from 1 to 3 mm. in diameter and pale rose in color. A medium reaction shows many vividly red papules surrounded by the normal skin. A strong reaction shows, in addition, changes of the total test area consisting in yellow brown pigmentation, indurative formation of plateaus, and marked reddening. A few or all of the papules may even show distinct formation of vesicles.

In weak reactions it is advisable to palpate the area in order to detect the follicles and to compare it with the area of the control.

The previously mentioned yellow pigmentation of the entire area is easily brought out by stretching the skin, whereas stretching the control area only blanches it.

The peak is reached after seventy-two hours, regardless of whether the test area was covered with adhesive tape for forty-eight or for seventy-two hours. This shows definitely that the reactive substances are absorbed by the skin within forty-eight hours and that the reaction of the skin to the absorbed material continues after the removal of the tape.

The color of the reaction begins to fade within ninety-six hours and is still faintly discernible up to one week. Medium reactions show a definite scaling up to approximately ten days; and in the marked reaction, even after two weeks, there may be roughening of the skin, brownish discolorations, infiltration, and scaling of the area.

In contradistinction to the intracutaneous test, there has never, thus far, been a generalized systemic reaction such as a rise in temperature, malaise, or focal signs.

Subjective symptoms accompanying the local reactions are mild. In nearly every positive case there is some itching over the test area, with only slight discomfort. In rare cases of very marked sensitiveness, slight pain over the test area may occur.

The ointment is stable and easier to apply, and it causes less psychic disturbance and fewer untoward general and focal reactions in the patient than does the old tuberculin used in the intracutaneous test.

The agreement between the ointment patch test and the intracutaneous test with tuberculin in all dilutions as performed on 190 children was 95.8 per cent.

The ointment patch test is generally comparable in results with an intracutaneous injection of 0.1 c.c. of old tuberculin, 1:100.

The ointment patch test produced markedly less nonspecific cutaneous irritation than the intracutaneous test.

**TUMOR GROWTH, "Heavy Water"** and, Woglom, W. H., and Weber, L. A. J. A. M. A. 102: 1289, 1934.

Deuterium, in the amounts that it was possible to administer as "heavy water," had no demonstrable effect on the growth of mouse sarcoma or mouse carcinoma.

**TETANUS: Development of Tetanus Antitoxin Following Administration of Tetanus Toxoid**, Sneath, P. A. T. J. A. M. A. 102: 1288, 1934.

Of 29 persons given three doses of tetanus toxoid, significant amounts of antitoxin developed in 28, a titer of at least 0.1 unit per cubic centimeter being reached in the majority, or 20.

From five to seven months after the last dose there was, in general, a reduction in the antitoxin level, but 27 still showed demonstrable antitoxin; and 25 showed 0.01 unit or more.

This suggests that active immunization with tetanus toxoid might be adopted advantageously by certain groups in whom the hazard of tetanus is greater than in the general population.

**MENINGITIS, Pneumococcic, Report of Case With Recovery Following Cisternal Drainage**, Bedell, C. C. J. A. M. A. 102: 820, 1934.

In a case of pneumococcic meningitis, Group IV, a drainage tube was inserted into the cisterna magna as soon as signs of meningeal invasion were observed. The tube remained in place for eight days; 200 c.c. of cerebrospinal fluid escaped daily by this route. Irrigations with physiologic solution of sodium chloride were carried out from the cisterna magna to the lumbar region. Periodic shrinkage of the brain volume was attempted by intravenous injections of hypertonic dextrose. The spinal fluid became secondarily infected with *Bacillus proteus* at the end of six days, producing a marked leucocytic response. There was progressive improvement, however, and the patient recovered completely and left the hospital at the end of seven weeks.

**GONOCOCCI, Preparation of Correct Picture and Simple Culture Method**, Szilvasi, J. Dermat. Wehnschr. Leipzig, 97: 1811, 1933.

To obtain the material for microscopic examination Szilvasi lets the patient urinate and then inserts a platinum loop into the anterior portion of the urethra and obtains a secretion that is readily spread out. After staining according to Gram's method, a striking picture is seen. Between monocytes and isolated threads of mucus, the gonococci are found in peculiar arrangements, in the form of coils, of clusters, or of wreaths or caps. The fact that an intensely stained zone surrounds the individual gonococcus enhances the peculiarity of the picture.

This method of obtaining the specimen of the urethral secretion is advantageous also for the culture of the gonococcus, a procedure which used to be rather difficult when the thick pus was used. The secretion is applied to the culture medium not in streaks, but in dots, and the gonococci are found on the margin of the dots. The facts that in the pus the majority of gonococci are either destroyed or impaired and that the phagocytic leucocytes contain other microorganisms are probably the reasons why the demonstration and culture are less successful when thick pus is used than when the secretion is used.

**ANEMIA, Aplastic, Greenwald, H. M.** Am. J. Dis. Child. 47: 360, 1934.

It is now generally conceded that aplastic anemia is a disease *sui generis* and is not a biologic variation of some form of primary or secondary anemia.

The most characteristic pathologic finding is a sulphur yellow appearance of the bone marrow instead of the reddish appearance one would expect to find in severe anemia. This is

due to a replacement of the normal marrow by ordinary fat tissue. In the case reported, the bone marrow was of a cranberry red appearance. Histologic examination showed, however, that the reddish appearance of the bone marrow was due not to active regenerative processes, but to hemorrhage. Histologic examination revealed a total absence of nucleated red blood cells and myeloid elements.

The blood picture is, of course, the main point of clinical diagnosis. There is a marked decrease in the hemoglobin content, with a diminution in the red blood cells to 1,000,000 or less; the hemoglobin is reduced to 10 or 15 per cent. The color index is approximately 1. Nucleated red blood cells are usually absent although occasionally observers have found isolated normoblasts. Reticuloocytes and polychromatophilic erythrocytes are absent. There is leucopenia with a marked reduction of the neutrophilic leucocytes and an almost complete absence of eosinophils. There is a relative increase in the lymphocytes. The differential count often shows the presence of only from 8 to 10 per cent polymorphonuclear cells while the lymphocytes are frequently found to be 90 per cent or over. Thrombocytopenia is constant and is a feature of the disease. The coagulation time is normal, but the retraction of the clot is interfered with, and the bleeding time is prolonged. In addition to the absence of normoblasts and megaloblasts, myelocytes, myeloblasts, or other forms of embryonic cells are usually absent. The results of the fragility test are usually normal; Lucas, however, stated that the fragility of the red cells may be altered, owing to the inability of the bone marrow to produce new red cells.

The blood serum is water clear. There is no increase in bile pigments. Urobilinuria is absent, and there is no increase in the urobilin content of the stool.

The course of the disease is rapid, and it is usually fatal before four months have elapsed. In fact, some observers refuse to regard the case of a patient who lives longer than six months as a true case of aplastic anemia.

Up to the present no therapeutic measure has proved satisfactory in the treatment of this disease. Repeated transfusion is generally recommended, but it is, at best, only a palliative measure.

**BLOOD SEDIMENTATION:** The Interrelation of Cutler, Linzenmeier and Westergren Tests, Greisheimer, E. M., Treloar, A. E., and Ryan, M. *Am. J. M. Sc.* 187: 213, 1934.

Blood sedimentation in 99 men and 102 women, selected without regard to age or health from university students and ambulatory patients, has been studied to establish the interrelationships between the Linzenmeier, Cutler, and Westergren methods. The average sedimentation in one hour for "normal" subjects appears to be reasonably concordant for the three methods despite the wide differences in tube width, anticoagulant concentration and length of fluid column, although the differences between the means for the three methods are significant statistically. The average sedimentation at one hour for the women is approximately double that for the men.

The concordance between the results by each pair of methods for the individual patients has been subjected to analysis by preparing the correlation tables. The regression lines, for predicting the most likely value to be expected by any one test when that by another is known, proved to be of three distinct types. There is a rectilinear relationship between the Cutler index and the Linzenmeier index. The regressions between Westergren index and Cutler or Linzenmeier index appear to be somewhat like saturation curves. However, they had to be fitted by a systematic scheme of free-hand graduations for lack of a suitable type of mathematical equation. The relationships between the various indices and Linzenmeier time values may be suitably portrayed by section of hyperbolas. Tables are provided for these average predictions for each independent variable of clinical interest.

The dispersals of individual cases about the lines of average relationship, although not studied in detail, are clearly greater than those ascribable to errors inherent in the technics.

The conclusion is clear that sedimentation measures for human blood are, in part, specific for the technic employed.

Standardization of a generally acceptable method for blood sedimentation would prove most advantageous for clinical work.

**TUBERCULIN TEST:** Value of the Negative Intracutaneous (Mantoux) Test in Adults, Lichtenstein, M. R. *Am. Rev. Tuberc.* 39: 190, 1934.

Complete insensitiveness to tuberculo-protein makes it certain that the patient is non-tuberculous, with the few exceptions given.

Complete insensitiveness is found in a sufficient number of adults to make the test worth while.

*Patients who react only to the strong concentrations of tuberculo-protein, with the same exceptions, almost certainly have no active tuberculosis.*

The test quickly excludes as nontuberculous a number of suspects, including some of the most difficult cases for diagnosis.

The intracutaneous test, carried into the stronger concentrations, should be a part of the diagnostic routine of every physician considering tuberculosis.

**PNEUMONIA, in Newborn and Stillborn Infants, Warwick, M.** *Am. J. M. Sc.* 187: 253, 1934.

Pneumonia in newborn infants is a definite entity and should be recognized by obstetricians, pediatricians, and pathologists. It usually begins in utero or during birth. The majority of the victims have physical handicaps; consequently, the pneumonia may be the result of lowered resistance. The exciting cause is as yet uncertain but seems to rest between bacteria contaminating the amniotic fluid or an irritating amniotic fluid, particularly when it contains large amounts of bile and cornified epithelial cells. Present evidence seems to favor the latter.

The facts favoring bacteria as the cause of pneumonia in the newborn infant are given:

1. Bacteria are usually the cause of exudation of polymorphonuclear leucocytes and of pneumonia.
2. Bacteria can be demonstrated in some of the pneumonic lungs.
3. In some, possible sources of infection are found, such as premature rupture of the membranes or light respiratory infections in the mother.
4. Some of the cases of pneumonia occur in groups during the months in which respiratory infections are the most prevalent.
5. Amniotic fluid is very frequently found in lungs where there is no evidence of pneumonia.

On the other hand, equally good reasons may be found for the possibility of uninfected amniotic fluid being the etiologic factor and these are also given below:

1. Chemicals may cause an exudative inflammation and also pneumonia.
2. A large percentage of cases show no demonstrable bacteria.
3. Masses of aspirated amniotic fluid are often found surrounded by numerous polymorphonuclear leucocytes in the midst of an atelectatic lung.
4. The pneumonia is often associated with atelectasis.
5. Amniotic fluid may vary markedly in constituents and in irritability.
6. Infants with other physical handicaps are often affected.
7. In some cases no convincing possibility of entrance of bacteria is seen.

**TULAREMIA, Treated by a New Specific Antiserum, Foshay, L.** *Am. J. M. Sc.* 187: 235, 1934.

An initial trial has shown that the goat can be made to yield a potent antitularemia serum which is effective in treating tularemia in man. The intravenous administration of this serum produced a marked and prompt amelioration of symptoms in 14 out of 15

tularemia patients and caused a shortening of the duration of adenopathy, the period of disability, and the total duration of disease. One patient, received in dying condition with extensive involvement of the lungs, liver, and spleen, was not improved. The antiserum has a specific desensitizing action. There is evidence to show that its beneficial effects in man are intimately associated with, and perhaps dependent upon, this property.

**ARTHRITIS, Rheumatoid, Blair, J. E., and Hallman, F. A.** Arch. Int. Med. 53: 87, 1934.

In a series of 57 cultures of synovial fluids and tissues from chronic multiple arthritis (55 from rheumatoid arthritis and 2 from Still's disease), a total of 41 (74.5 per cent) remained sterile and 14 (25.4 per cent) yielded positive cultures. The microorganisms obtained in the positive cultures included streptococci, diphtheroid bacilli, gram-positive cocci incapable of growth on subculture, and an occasional gram-negative bacillus associated with the aforementioned bacteria.

In a series of 175 cultures of synovial fluids and tissues from a variety of chronic infectious and noninfectious conditions of the joint other than rheumatoid arthritis, 142 (81.1 per cent) were sterile and 33 (18.8 per cent) were positive. The positive cultures included *Staphylococcus aureus*, indifferent streptococci, gram-positive cocci incapable of growth on subculture, and diphtheroid bacilli.

No direct etiologic significance is attached to any of the organisms obtained in this series.

It is felt that at the present time no specific bacteriologic agent may be considered to have been demonstrated as the etiologic cause of rheumatoid arthritis, particularly in view of the multiplicity of results and the lack of general confirmation of any one report.

**BLOOD, in Normal Pregnancy, Dieckmann, W. J., and Wegner, C. R.** Arch. Int. Med. 53: 71, 1934.

Previously reported values for blood and plasma volumes in pregnancy are at variance with each other, and the results are inconclusive because of the different methods used and the method of calculation. The volumes are reported either in cubic centimeters per kilogram or in percentage of body weight, either of which is unreliable because of the constantly changing weight in pregnancy.

Determinations of the blood and plasma volumes were made on various groups of women for the different periods of pregnancy. The cubic centimeters per kilogram and the means for the different periods were calculated, and although there is a slight increase at term, statistical analysis indicates that the changes are of no significance.

Similar studies in which the same women were followed throughout pregnancy and the puerperium indicate that the following changes occur:

1. The blood and plasma volumes begin to increase in the first trimester, and by the thirteenth week the gain amounts to 16 per cent and 18 per cent, respectively.

2. At term the average increase in the blood volume is 23 per cent and the plasma 25 per cent. This change is designated an "oligoeythemie hypervolemia." Although this increase seems large, losses of blood of 700 c.c. or more are at once manifested in measurable reductions in volume. The pregnant woman survives losses of blood which would be fatal if she were not pregnant, partly because of the increase in blood volume, but more particularly because of the tremendous amount of fluid in her tissues.

3. At eight weeks postpartum there is an average decrease of 16 per cent for both blood and plasma volumes. This does not quite equal the increase, but, since most of the patients weigh more after pregnancy, the discrepancy is explained.

4. The increase in blood and plasma volumes is not merely to fill vessels but is probably a part of the mechanism required to permit proper fetal respiration.

**PNEUMONIA**, Epidemiology of Lobar, Smillie, W. G., and Leeder, F. S. *Am. J. Pub. Health* 24: 129, 1934.

Nasopharyngeal cultures from 264 contacts of 64 cases of lobar pneumonia due to Type I and Type II pneumococcus have been studied. The results indicate that 20 per cent of the immediate family contacts of these patients harbored the homologous strain in their nasopharynges. The hospital contacts of the same patients, however, were seldom infected (about 2 per cent). These results suggest that it is quite justifiable to treat cases of lobar pneumonia due to Type I and Type II pneumococci in the open wards of general hospitals.

One experiment indicates that a healthy carrier of Type I pneumococcus does not transmit this organism to immediate contacts, even though the individuals are living under overcrowded conditions.

The evidence suggests that there is some additional factor other than simple contact which determines the transfer of Type I or II pneumococci from a patient with lobar pneumonia to contacts. Nineteen of the 25 family contacts of cases of lobar pneumonia due to Type I or Type II pneumococci that became homologous carriers were suffering from acute colds at the time the cultures were taken. Positive cultures were found as frequently on the first day of exposure as after a week. This evidence suggests that family epidemics of colds may be a factor which determines the transfer and establishment of Type I and Type II pneumococci from the infected to the uninfected.

Carriers of Type I and Type II pneumococci, when once established, may continue as carriers of these strains for a considerable period of time without giving rise to lobar pneumonia in themselves or their contacts and without producing a second group of carriers.

**MILK**, Examination of for Members of the *Escherichia-Aerobacter* Group, McCrady, M. H., and Archambault, J. *Am. J. Pub. Health* 24: 122, 1934.

Comparative results obtained from examination of milk samples for *Escherichia-Aerobacter* by various methods suggest the following tentative conclusions:

1. So-called "typical" colonies appearing in solid media pour-plates inoculated with milk may not be accepted as colonies of *Escherichia-Aerobacter* unless a sufficiently thorough examination of a large number of colonies from representative samples has proved that they may be so accepted. In the hands of the authors, plates poured with neither Endo, bile salt, nor eosin methylene blue agar proved reliable for direct enumeration of colon organisms in milk samples since the proportion of resulting typical colonies which were confirmed varied from zero in some samples to 100 per cent in others. It is quite probable that similar difficulties would be encountered in the examination of dairy products other than milk by these plate methods.

2. The production of 10 per cent or more gas in brilliant green bile 2 per cent special fermentation tubes inoculated with quantities of raw or pasteurized milk varying from 10 c.c. to 0.001 c.c. and incubated forty-eight hours at 37° C. provides reasonable assurance of the presence of *Escherichia-Aerobacter* organisms. This medium appears to be as reliable as gentian violet bile for the enumeration of these organisms and is more conveniently employed in those laboratories where it is also used for examination of water samples. The percentage of such brilliant green bile presumptives which were completely confirmed varied as follows:

|                                        |              |
|----------------------------------------|--------------|
| Raw milk, 1 c.c. to 0.001 c.c.         | 99 per cent  |
| Pasteurized milk, 10 c.c.              | 100 per cent |
| Pasteurized milk, 1 c.c. to 0.001 c.c. | 86 per cent  |

It is pointed out that since the organisms in 10 c.c. of properly pasteurized milk rarely produce gas in this medium, the production of any amount of gas from the majority of such samples of 10 c.c. or less of a pasteurized milk is usually indicative of some fault in the processing of the milk, either improper pasteurization or recontamination of the pasteurized product.

### Developments in the Study of Agglutinins

THE bacteriologist of the future will, without doubt, look back with envy upon the days when dogma was supreme, when bacterial species were immutable, and any variation from the accepted type was dismissed with complacence as an "involution form."

Indeed, it is quite possible that this attitude may even be encountered among the bacteriologists of today, confronted as they are with a confused array of "rough" and "smooth" colonies with H's and O's thrown in for good measure!

At first regarded as of purely academic interest, later studies have shown quite definitely that these bacterial variations have a very definite and perhaps wide application to the practical problems of bacteriology, immunity, and epidemiology and cannot be disregarded in the utilization of agglutination reactions in the study of disease.

Among the oldest and perhaps also the most commonly applied agglutination test is that devised by Widal for the study of typhoid fever; certainly it is perhaps the one most familiar to the practitioner at large and because of the fact that large numbers of the general population have now a history of antityphoid vaccination as an aftermath of the World War, general concepts as to the clinical interpretation of positive Widal reactions have, perforce, been the subject of renewed study and modification which it may be of some interest to summarize and review.

The occurrence of agglutinins for the typhoid group, as well as for other organisms, in nonvaccinated, supposedly normal individuals has been studied by numerous investigators interested, not only in their occurrence but in the explanation of their presence.

Perhaps the majority of observations in this field support the view that the occurrence of such agglutinins is the result of previous exposure to the specific infectious agent, either through vaccination or as a result of natural clinical or subclinical infection.

Havens and Mayfield<sup>1</sup> in a study of 1,136 such individuals encountered 263 positive reactions or 23 per cent, 14 per cent in a dilution of 1:40; 6 per cent in a dilution of 1:80, and 3 per cent in a dilution of 1:160, results comparable to those of other and previous investigators.

These so-called "normal" agglutinins behaved in the same manner and were in all respects indistinguishable from specific antibodies. As in only 60 of the 263 positive reactors was it possible to obtain any information concerning any previous attack of clinical typhoid fever or of prior vaccination, 48 having no such history, it must be assumed that, if these 60 may be taken as a fair sample of the group, only 20 per cent of all positive Widal reactions represent the aftermath of vaccination or clinical typhoid fever.

Other observers, however, have reported the apparent nonspecific production of typhoid agglutinins. For example, Kilduffe and Hersohn<sup>2</sup> demonstrated the presence of typhoid agglutinins in 29 per cent of 200 serums from tuberculous patients, only 33 per cent of those reacting having any history of previous vaccination or clinical typhoid fever.

In the interpretation of such reactions various possibilities must be taken into account: They may be either nonspecific or heterologous; they may represent the result of an unrecognized or subclinical typhoid infection in the past and, as such, an expression of the reawakening of a previous specific antigenic stimulus, or they may exemplify, as indicated by the observation of Gilbert and Coleman,<sup>3</sup> the fact that exposure to certain bacterial types will again initiate production of apparently unrelated antibodies such as have developed previously in response to an antigenic stimulus of different nature.

While there may be room for discussion as to the nature and mechanism of such reactions, there can be no question that they may definitely complicate the interpretation of diagnostic agglutination tests.

In view of the findings above referred to it is, or should be, obvious that the trend of a series of agglutination reactions furnishes evidence much more clear-cut and definite than that obtainable from a single test, just as the trend

of a series of leucocyte counts is of far greater value than the results of a single determination. Nevertheless, in by far the greater majority of instances, clinical investigations do not include such serial studies and clinical inferences, and deductions must stand or fall upon the results of a single agglutination test.

Under these circumstances it is fortunate that studies in bacterial mutation and variation have demonstrated a relation between this and the response of the organisms to agglutinins and that evidence is accumulating which suggests that even a single agglutination test may furnish reliable information when interpreted in the light of these newer investigations.

That variations may occur in colonies of a pure culture of a single bacterial species was long ago recorded, but it is only within comparatively recent times that it has been appreciated that these variations are indicative of variations in antigenic structure and of variation in the production and the response to agglutinins.

The starting point of these investigations may be said to be the work of Weil and Felix<sup>1</sup> who first demonstrated the existence of dual antigens in many bacteria and showed their relation to variations in the character of their colonies, for while the observation had been recorded before by the English workers Smith and Reagh and Beyer and Reagh, it passed almost unnoticed until the work of Weil and Felix in 1917 and their later publication in 1924 demonstrated its practical importance in the interpretation of agglutination reactions.

During the study of the anomalous Weil-Felix reaction (the agglutination of a particular strain, *Proteus* X19, of proteus organisms by the blood of patients suffering from typhus fever), these workers recorded first, that there occurred two types of colonies in the proteus cultures; second, that these two types presented differing agglutinogenic properties, and, finally, that the clinical interpretation of agglutination reactions was affected by and related to these differences.

The normal, flagellated proteus bacillus produces a thin, spreading growth spoken of as the "exhalation" (Hauch) form, while the nonflagellated variant presented isolated colonies without exhalation (Ohne Hauch), terms soon shortened to O and H.

Later developments demonstrated that the agglutinogenic properties of these O and H forms were different, the antigens—"H antigens" produced by the H forms being flagellar in origin and thermolabile while those produced by the O forms were thermostable and of somatic derivation.

The subsequent studies of numerous investigators showed that dual antigens were present in many bacteria among them the organisms of the typhoid group.

The colony variation in bacteria of this and other groups not being of the same character as those seen in the proteus group, are spoken of as "smooth" and "rough" abbreviated, for convenience, to "S" and "R."

As yet, however, there is lacking any clear definition of the exact meaning of "smooth" and "rough" as applied to bacterial colonies so that, in the interests of exact terminology it has been suggested that they be replaced by "matt" and "glossy."

The main differences, however, are in general as follows: the "smooth" (or glossy) colony is round, shining, translucent, reticular, and of smooth appearance, while the "rough" (or matt) colony is of an irregular or jagged contour, somewhat more opaque to transmitted light, and presents the appearance of a rough, matt surface.

Studies of these S and R forms showed no appreciable differences in their morphologic or biochemical reactions but very profound differences in other characteristics which may be summarized in tabular form as follows:<sup>5</sup>

#### SMOOTH TYPE

1. Emulsions stable in 0.85 per cent NaCl.
2. Growth uniformly turbid in broth.
3. Motile (in the case of flagellated bacteria).
4. Agglutinated by specific serum in large flocculent clumps.

#### ROUGH TYPE

1. Agglutinated by 0.85 per cent NaCl.
2. Growth forms sediment with clear supernatant fluid.
3. Motility often reduced or absent.
4. Agglutinated in small compact granules falling to the bottom of the tube.

These differences in the type of agglutination secured with S and R forms are of particular and practical importance in relation to diagnostic agglutination reactions and have been rather extensively studied, as a result of which rather definite information is accumulating.

O agglutination is granular, forms slowly, settles slowly, and presents flakes of fairly small and uniform size, leaving a clear supernatant fluid with a scanty sediment difficult to dislodge.

H agglutination, on the contrary, forms rapidly and settles rapidly, is flocculent in character, the flakes being in general large, though varying in size, and the supernatant fluid is cloudy while the sediment is voluminous and easily dislodged.

According to the observations of Weil and Felix<sup>4</sup> the agglutinins produced after inoculation with heat-killed vaccines are mainly of H type while those formed as a result of an actual attack of the disease are mainly of O type.

The practical importance of such a conclusion applied to diagnostic agglutination reactions has very naturally led to many studies.

Eldering and Larkum<sup>6</sup> from a study of 419 tests conducted with both O (alcohol-killed) and H (formalin-killed) antigen suspensions found the assumption relatively accurate, residual O agglutinins being present in quantity only after actual infection, although, of course, it must be borne in mind that the type of agglutinins following vaccination will naturally be in some measure dependent upon the preponderance of O or H antigens in the vaccine used.

Other observations<sup>7, 8</sup> are also corroboratory of these conclusions so that, while further observations and the study of large series should still be carried

on, the formulation of the following tentative dieta seems justified with regard to the diagnosis of enteric fevers by means of agglutination reactions:

1. As it has been conclusively demonstrated that both H (flagellate) and O (somatic) agglutinins are produced in most cases of typhoid fever it is advisable that agglutination tests be conducted with both H (formalin-killed) and O (alcohol-killed) antigen suspensions.

Dulaney, Wickle, and Trigg<sup>7</sup> from their studies prefer 1 per cent formalinized suspensions because the concentration inhibits the O agglutination.

2. The titer of the O agglutination is of definite value although further investigations will probably be required to determine the exact status of low titer reactions, concerning which there has been some discussion.

Felix originally suggested an agglutination titer of 1:100 or 1:200 as strongly suggestive if not diagnostic of infection. Dulaney, Wickle, and Trigg, however, finding such titers exceeded by 23 per cent of their nontyphoid cases, suggest that the titer be raised to 1:500 before being regarded as diagnostic.

On the other hand others, among them Gilbert, Coleman, and Laviano<sup>8</sup> regard agglutination in a 1:80 titer of distinct significance.

3. From the foregoing it follows that all diagnostic agglutination tests should be quantitative in character and devised to determine the highest titer in which agglutination occurs which, indeed, has long been the custom of most laboratories and should be the rule in all.

While all that has been said thus far applies to the Widal reaction in its application to the study of typhoid fever, it is important to emphasize that in principle as well as practical application it applies also to all agglutination tests or reactions.

It is essential also to recognize that the term "enteric fever" must be recognized as a generic term and as a clinical rather than a bacteriologic entity. For it is now recognized that there are at least twelve species within the *Salmonella* group which, though more commonly associated with acute gastroenteritis, are likewise capable of producing a continued fever in man. In addition to these, experience shows that in a possible explanation of continued fever in the human being both undulant fever and tularemia must be remembered.

This is of practical importance as concerns the selection of antigen suspensions against which the serum should be tested, in the determination of which several factors must be taken into consideration. In addition to the typhoid group (T, A, and B) the routine inclusion of abortus suspensions will be found of value, while the use of a *B. tularensis* suspension may either be routine, where this disease is encountered with any frequency or reserved for such cases in which this disease is regarded as a diagnostic possibility. This same principle applies also to the infrequently encountered *B. paratyphosus C* (in the United States, at least), as well as to *B. enteritidis* and the other occasional causes of enteric fever. While it is suggested above that paratyphoid A suspensions constitute one of the routine antigens, this infection is so infrequently encountered that its inclusion is a matter of choice.

From a consideration of the available evidence, and the literature on this subject is assuming quite respectable proportions, it appears that: The determination of both somatic (O) and flagellar (H) antigens is advisable; and that the determinations have their most definite value when they are quantitative.

The question is of interest not only to the laboratory worker by whom the determinations are made but as well to the clinician by whom they are requested and who, in the majority of instances, will be responsible for their interpretation and clinical application.

The interpretation of agglutination reactions is governed by many factors in addition to those already discussed.

As agglutinins in enteric fever do not reach their maximal titer as a rule before the sixteenth to the twenty-first day, although they usually begin to appear during the first week, it follows that a negative reaction during the first week is of little diagnostic significance. It is not, however, valueless because it affords a valuable base line for comparison of any future fluctuations which may occur.

While, with repeated tests, 98 per cent of typhoid fever cases show the presence of agglutinins at some time during the course of the disease, and while, when both O and H antigens are used, the absence of a significant rise in the titer is exceptional, the incidence of positive reactions on a single test is accepted as that laid down by Park and Williams, namely: first week, 20 per cent; second week, 60 per cent; third week, 80 per cent; fourth week, 90 per cent.

In the interpretation of single reactions one must also take into account the frequency and concentration of H and O agglutinins both in the serum of the normal population and in subgroups differentiated by some particular experience, such as past epidemics or antityphoid vaccination. This, of course, varies in different localities.

It appears, however, that O agglutinins in low titer (1:20 to 1:50) are more common than H agglutinins in the normal nonvaccinated population, and likewise that T.A.B. vaccination results in a higher titer of H than O agglutinins.

In general, therefore, it may be concluded that a reaction of 1:80 with an alcohol-treated (O) antigen suspension usually suggests typhoid fever or an infection with a closely allied bacterial species, while a similar reaction with a formalinized (H) antigen suspension suggests several alternatives: that the patient has typhoid fever; that he has had the disease in the past; or that he has been vaccinated.

The principles governing the interpretation of agglutination reactions in enteric fever have been well summarized by Topley<sup>10</sup> and are here paraphrased:

1. A negative reaction to all the antigen suspensions used for the test may signify: (a) that the patient does not have enteric fever; (b) that the specimen has been taken before agglutinins have appeared in the blood; or, (c) that the enteric fever is of unusual type and caused by an organism not represented in the suspensions employed in the test.

The first two alternatives are differentiated by a repetition of the test at suitable intervals; the third requires further investigation directed especially toward detection of the organism by culture.

A negative reaction in the second or third week of the illness is of definite negative diagnostic value and repeated negative reactions render the correctness of the clinical diagnosis unlikely.

2. A positive reaction against any suspension must be considered in terms of: (a) the distribution of agglutinins among the normal population; (b) the stage of the disease at which the test was made; and (c) the history as regards vaccination.

A positive reaction of 1:40 or over in a nonvaccinated individual is of definite significance and probably not an expression of "normal" agglutinins

3. As is the case with many other laboratory procedures, the trend of a series of agglutination tests is often of more value than a single reaction, especially in the case of those who have had antityphoid vaccination, any significant rise from the original titer having a decided significance.

### GLUTATHIONE CONTENT OF BLOOD IN CHRONIC ARTHRITIS AND RHEUMATOID CONDITIONS

---

BEN D. SENTURIA, M.D., ST. LOUIS, MO.

---

THE encouraging therapeutic results obtained with parenterally given colloidal sulphur in cases of chronic nonspecific arthritis and rheumatoid conditions<sup>1</sup> prompted this investigation as a first step in the study of sulphur metabolism in these diseased states. Since the discovery of glutathione by Hopkins in 1920, much work has been centered around this interesting sulphur compound which represents a thermostabile oxidation-reduction system, and which is assumed to have some important part in the physiologic oxidation-reduction processes of the cells. Normal human blood contains from 30 to 40 mg. of glutathione per 100 c.c.; it seemed of interest to investigate whether or not possible derangements in the sulphur metabolism of our patients are expressed in abnormal glutathione values. By the method described below, the amounts of glutathione were determined in the blood of 28 healthy individuals, of 27 patients with hypertrophic arthritis, of 18 with atrophic arthritis, and of 8 with bursitis and peri-arthritis (fibrositis). At the close of this experimental work it was noted that the Arthritis Committee of the British Medical Association in a recent report recommended this subject, among others, for research in the study of arthritis.<sup>2</sup>

## ANALYTICAL METHOD\*

For the determination of reduced glutathione in blood, Tunncliffe introduced the iodometric titration of blood filtrates obtained by deproteinization with trichloroacetic acid.<sup>3</sup> Numerous modifications of this method were evolved, mainly because iodine oxidizes under prevailing conditions not only glutathione but also ergothioneine, another substance with a sulphhydryl group always present in blood. Woodward and Fry<sup>4</sup> made the valuable observation that at high degrees of acidity and low temperature only a small fraction of ergothioneine is affected by iodine. In this laboratory it was found that the presence of a considerable excess of potassium iodide during titration further depresses the iodine consumption of ergothioneine, so that error from this source becomes negligible. The assertion of Woodward and Fry, that in the Folin-Wu method of deproteinization reduced glutathione is rapidly oxidized due to the slight acidity of the filtrate, was not substantiated. No change was found when the Folin-Wu filtrates were allowed to stand for as long as three hours; even after standing all night at room temperature the decrease in reduced glutathione was but slightly over 20 per cent. This observation agrees with that of Benedict and Gottschall<sup>5</sup> who worked with

\*This method was devised by Dr. Michael Somogyi under whose guidance the analytical work was carried out.

blood filtrates of about the same acidity as that of the Folin-Wu filtrates. In the iodometric titration the excellent Okuda technic<sup>6</sup> was adopted.

The analytical procedure, accordingly, has the following course: Protein-free blood filtrate is prepared by a slightly modified Folin-Wu method<sup>7</sup> in 1:10 dilution; separate the precipitate without undue delay by centrifugation, pour the protein-free fluid through a dry filter paper. Pipette 20 c.c. of the filtrate (which corresponds to 2 c.c. of blood) into an Erlenmeyer flask (100-150 c.c.) and add 1 c.c. of N/1 sulphuric acid. (At this stage the sample may be allowed to stand until a convenient time for titration.) Before titration, introduce 0.3 gm. of potassium iodide and 3 drops of 0.5 per cent starch solution (Lintner's soluble starch), cool the mixture in ice water and from a microburette titrate with 0.0025 N potassium iodate, or biniodate, until the faintest perceptible blue color becomes permanent.

$$\frac{\text{c.c. iodate used} \times 307}{8} = \text{mg. reduced glutathione per 100 c.c. of blood.}$$

All the reagents employed in this analysis keep indefinitely. One-tenth normal potassium biniodate may be prepared as stock solution and 1:40 dilutions of it made from time to time. The potassium iodide may be added in the form of 3 c.c. of a 10 per cent solution but it must not be older than one day.

The results of our experiments are presented in Tables I to V.

Since the entire glutathione content of blood is confined exclusively within the corpuscles, we have expressed the values both for 100 c.c. of whole blood and for 100 c.c. of corpuscles. Influenced by the same consideration, Gabbe<sup>8</sup> calculated the relation between glutathione and red cell count, while Woodward and Fry attempted to correlate the glutathione and the hemoglobin content. In my opinion, however, none of these forms of expression contributed added information beyond the figures given for whole blood.

The reduced glutathione content of the blood of healthy individuals, calculated for whole blood varied in these experiments between 29 and 49 mg. per 100 c.c., with an average of 36.5 mg. Woodward and Fry<sup>4</sup> obtained with their own method 34, Benedict and Gottschall<sup>5</sup> with a colorimetric procedure found 35 mg. as the average values which are in close agreement with ours.

#### CONCLUSION

The tables disclose, without need for comment, that the glutathione content in the blood of 27 patients with hypertrophic arthritis, of 18 with atrophic arthritis, and of 8 with fibrositis, compared with that in the blood of 28 normal individuals, shows no appreciable deviations either in regard to the range of variations or in the average values.

## PNEUMOCOCCUS CHAIN FORMATION\*

ITS RELATION TO VIRULENCE IN MICE, OCCURRENCE AND DISTRIBUTION BY  
PNEUMOCOCCUS TYPES IN HUMAN RESPIRATORY INFECTIONS, AND ITS  
RELATION TO PROGNOSIS IN LOBAR PNEUMONIA

JESSE G. M. BULLOWA, M.D., AND CLARE WILCOX, NEW YORK, N. Y.

LONG chains of pneumococci in the broth inoculated with the organisms producing the septicemia of mice, resulting from inoculations with pneumonic sputum is a striking phenomenon; its occurrence and significance were studied by us during the period from 1929 to 1933. It seemed to us that there is some correlation between the severity of the disease in patients and the finding of growth of this character in cultures of pneumococci recovered from sputum, lung juice and blood cultures. The microscopic observation of all cultures is imposed by the method of typing employed in our laboratory.

Organisms in the stained smear of the sputum cannot, without further tests, be conclusively classified as pneumococci even though they resemble pneumococci. The determination of their solubility in bile necessitates waiting for the culture.

Chain formation, or chaining of pneumococci, has been observed since 1893 when B. Issaef<sup>1</sup> and J. Washbourn<sup>2</sup> found that pneumococci formed chains when they were grown in homologous specific immune sera. Similar observations were made on *B. pyocyaneus* by Charrin and Roger (1889)<sup>3</sup> and on *B. coli* and *B. proteus* by Pfaundler.<sup>4</sup> When *B. coli* and *B. proteus* grew chainwise the organisms were club-formed, convoluted and stained unevenly, some failing to take the stain. The usual turbidity was present in cultures grown in broth with normal serum, but in the presence of specific immune sera, there was a heavy turbidity in the bottom of the tube and the broth was clear. The normal morphology and cultural characteristics of the organisms were restored by reseedling them in the usual broth.

A study of the relation of chain formation to virulence of the pneumococci in mice was undertaken. Pneumococcus Type IV (Cooper) cultures recovered from Case 4,613 were passed through mice daily for eight days. One cubic centimeter of the eighteen-hour culture from the mouse heart's blood was used. With each succeeding passage the chains became shorter; on the eighth day there were only occasional short chains of from three to five diplococci. The rest were in pairs. The first mouse lived twenty hours and the eighth mouse only seven hours.

A Type I culture isolated from Case 4,717 was passed through mice nine days before the chains completely disappeared. The first mouse lived for

\*From the Littauer Pneumonia Research Fund of New York University, Harlem Hospital Station, and the Medical Service, Harlem Hospital (Department of Hospitals, New York City), T. A. Martin, M.D., Director.

Received for publication, November 14, 1933.

twenty-six hours, and the ninth mouse nine hours. A Type IX culture obtained from Case 1,408 was passed in the same manner for seven days. The first mouse lived thirty hours and the seventh died at the end of eleven hours.

A Type V culture isolated from Case 30,593 was passed through mice for four days. The colonies were "rough" when first isolated and remained so after the mouse passages. The culture continued to grow in chains. The culture from the heart of the fourth mouse failed to grow, though the mouse died. Because of the pressure of work the inoculation with the culture from the third mouse was not repeated and the series of inoculations continued.

A blood culture, Type VIII, isolated from Case 30,912, was streaked on agar plates to study the colonies. The edges were found to be irregular and

Fig. 1.—A. Pneumococci growing in chains, from mouse's heart culture. B. Agglutination with homologous serum, of pneumococci growing in chains.

the centers depressed. Broth cultures had a puff-ball growth in the bottom of the flask with some stringlike growth extending upward to the top of the broth.

A blood culture isolated from Case 21,755 gave rough colonies and the broth cultures were very granular.

Fig. 1 shows the characteristic appearance of the chain formation which extends in some instances entirely across the field with occasional separate organisms and the typical tangled skeins found in agglutination tests with pneumococci in chains. It is noteworthy that the organisms are small with ill-defined capsules.

#### CLINICAL OBSERVATIONS

Our experience seems to show that where chainwise pneumococci were present, the cases were usually less severe than the average case. During

the period of the study there were 1,152 pneumonias in adults, of whom 49 presented pneumococci in chains, an incidence of 4 per cent, and 191 pneumonias in children, of whom 7 gave pneumococci in chains, or 3 per cent.

The occurrence of the chain formation was distributed by type, as indicated in Table I. Among 145 cases from which *Pneumococcus* Type V (Cooper), Subtype IIa of Avery, were recovered, 18 strains which grew as chains were isolated, or 14 per cent, and among 76 cases of Type VIII (Cooper), atypical III of Sugg, Gaspari, Fleming and Neill,<sup>3</sup> pneumococci in chains were isolated from 6 patients, or 8 per cent. Chain formation did not occur among 163 cases of lobar pneumonia due to *Pneumococcus* Type II.

The monthly distribution of this cultural appearance during the year is shown in Fig. 2. Apparently the number of strains having chain formation

Fig. 2.—The occurrence of pneumococci growing in chains by months. The appearance of chains was most frequent when the cases were most numerous, and not in the summer time when the milder cases are more frequent. Each square is a case.

were in proportion to the number of cases, i.e., appeared most frequently when there were most cases. There were few chain-wise organisms encountered during the summer and fall months when the pneumonias are generally thought to be milder. The incidence commenced to fall when the cases were still numerous and severe in March.

It is significant that chain-wise formation was found in half the cases before the sixth day of illness. In some of the cases, our initial observation was later than that.

The only exception to the usual good prognostic correlation of the chain-wise appearance were the cases in which involvement with pneumococci of different type, which did not form chains (Case 4,915), or streptococci invasion (Case 4,808) supervened, and in two of the five bacteriemic cases.

TABLE I  
DISTRIBUTION BY TYPES OF PNEUMOCOCCUS CULTURES GROWING IN CHAINS; CULTURES ISOLATED FROM LOBAR PNEUMONIA CASES AND FROM OTHER RESPIRATORY INFECTIONS

|       |    |              |    |
|-------|----|--------------|----|
| I     | 9  | XIX          | 8  |

| Total cases                       |        |          |         | 92    |

The only cases, however, in which the organisms probably responsible for death were found in chains (because there was no change of pneumococcus type) are Cases 4,612 and 25,654. In Case 4,612 the organisms were in chains in the first blood culture; in the second blood culture the pneumococci grew in chains. Subsequent blood cultures were sterile. The patient received serum, agglutinins appeared and persisted. The final increase in pulse rate may have been associated with a terminal invasion but postmortem cultures were not taken. There was very marked dehydration. Case 25,654 had a positive blood culture of pneumococci in chains on admission, Sept. 24, 1932. Subsequent blood cultures were positive on some days and negative on other days. The cultures did not grow in chains in those made after Oct. 5, 1932.

TABLE IV

A COMPARISON OF THE MORTALITY IN PNEUMONIA CASES CAUSED BY PNEUMOCOCCI OCCURRING IN CHAINS AND BY PNEUMOCOCCI NOT IN CHAINS

\*The asterisk indicates bacteremic cases.

required infrequently. The illness seemed to be shorter than usual. The blood counts were neither high nor extremely low, with the exception of one case (2,188) in which tuberculosis was associated, where the blood count was 7,000. There were no complications with the exception of otitis media, and an empyema which was present on admission. No attempt to give a percentage of the occurrence of the various symptoms is made because too little is known concerning the occurrence of such symptoms when pneumonias are studied and divided into their separate types.

#### FATAL CASES

The patients who died are worthy of special consideration. There were four deaths in this group of cases.

CASE 4,915.—A *Pneumococcus* Type III in chains was recovered from this patient's sputum on admission, and later agglutinins for Type III were demonstrable in his blood. This patient probably acquired a Type VII pneumococcus infection from a pneumonia patient with a severe *Pneumococcus* Type VII bacteremia, who was placed in the bed next to him on the twentieth day of his illness. The temperature continued high and the patient became worse, dying on the twenty-sixth day. A Type VII pneumococcus was recovered from a lung suction culture on the day before death. Postmortem heart's blood cultures revealed a

*Streptococcus hemolyticus*. This case probably should not be counted as a death from the *Pneumococcus* Type III infection from which he had apparently recovered, having produced agglutinins, but a death from a virulent Type VII pneumococcus and a hemolytic streptococcus. It may be that a very severe clinical picture associated with a pneumococcus growing in chains should suggest that the condition possibly is due to a different organism which should be sought by further study.

CASE 4,612.—This patient had a Type V pneumococcus blood culture on admission. The organism grew in chains in the initial blood culture. The second blood culture was positive but the organisms were not in chains. All subsequent blood cultures were sterile. Marked dehydration was present throughout the illness and the patient died on the twelfth day of illness. Agglutinins for the invading organism developed and persisted. There were no pneumococci in the single sputum examination.

CASE 4,808.—Type I. This patient continued to have a high temperature, and six sputum examinations were made. In the sputum streptococci were found, as well as Type I pneumococci in chains. The results of the sputum examinations were as follows:

1. Neither pneumococci nor streptococci were recovered.
2. Streptococci.
3. No growth in mouse peritoneum.
4. Pn. Type I in chains.
5. Pn. Type I in chains.
6. Streptococcus.

This patient died on the fourteenth day and *Streptococcus hemolyticus* was recovered from the postmortem heart's blood. Two previous blood cultures taken on the third and tenth days of the illness were sterile. This patient received large amounts of *Pneumococcus* Type I serum without favorable result. The streptococci were probably of major importance, and account for the death.

CASE 25,654.—Type V. The blood cultures have been described (p. 1159). Fluid was obtained by chest tap on October 11. The patient died in pulmonary edema Oct. 13, 1932.

Seventeen of the patients received type specific serum. Seven of these were Type I, 7 Type V, 2 Type VIII, and one Type XIII. In other than Type I, experience with dosage is too limited to definitely determine the average amount required. From analogy with Type I the amounts which were efficient in all but three of the patients appear to be moderate as they were less than 50,000 units in eight instances. One hundred thousand units is our usual dose for Type I. Case 4,753, admitted on the second day, received 185,000 units of Type I serum. A gradual fall of temperature occurred on the seventh day. There had been a critical fall of pulse on the third day, and of temperature on the fourth day, the former after 25,000 units and the latter after 55,000 units. The defervescence did not last and the agglutinins did not persist in the blood. A small amount of fluid was removed. Empyema did not develop.

#### SUMMARY

1. The phenomenon of chain formation in pneumococci and its association with "rough" colonies and lowered virulence for mice is described.
2. Pneumococci growing in chains occurred in 4.2 per cent of the adult pneumococcus pneumonias, and in 3.4 per cent of the childhood pneumonias.

It occurred in 14 per cent of all Type V pneumococcus pneumonias, in 8 per cent of all Type VIII pneumococcus pneumonias and in 5 per cent of all Type XIII cases.

3. The occurrence of chain-wise growth of pneumococci in severely ill patients suggests the possibility that the infection may be due to some other organism, either a streptococcus or a pneumococcus of another type. Chain-wise appearance occurring in pneumococci recovered from the blood should not be a deterrent to the use of available specific serum as the appearance of chain formation may be due to a partial protection in the blood. This protection may become exhausted.

4. The cases for the most part appear to be less severe than pneumonias due to pneumococci which do not form chains.

The authors record their appreciation of the criticism and suggestions of Dr. William H. Park and Georgia Cooper.

## OBSERVATIONS ON OXYGEN THERAPY\*

LOUIS N. KATZ, M.D., CHICAGO, ILL.

WITHIN recent years oxygen therapy has become increasingly popular in clinical practice, and has proved of definite value in helping certain patients. But the question has arisen whether its more widespread use is entirely deserved. The problem can be approached in one of two ways: (1) by making a statistical summary of its effects based on clinical impression; and (2) by determining its action on the various functions of the body in controlled experiments on a few subjects, and from such determinations estimating the possible benefit in various types of illnesses. This is not the place to enter into the relative merits or limitations of the two types of approach. The recent studies on oxygen therapy with which the author was associated<sup>1, 2, 3, 4</sup> were based on the latter method, and this method of approach will be followed in this communication.

It is definitely established that oxygen is essential for the life and well-being of all body cells. Its removal or diminution is detrimental to all cells, affecting some more rapidly than others. The cells contain practically no store of oxygen and are, therefore, entirely dependent on the oxygen brought to them in the capillaries. In many diseases an interference with the oxygen supply to the tissues occurs, a condition known as anoxemia, or more accurately, anoxia. Anoxia may be localized to one region or may be general throughout the body. It may be mild, moderate, or severe in degree; it may be acute, subacute or chronic in time; and it may be one of several varieties. Barcroft<sup>5</sup> recognized three forms of anoxia: (1) The anoxic form in which the oxygen want of the tissues is due to an imperfect aeration of the arterial blood so that the blood reaching the capillaries does not carry oxygen up to its full capacity. (2) The anemic form in which the arterial blood carries its full capacity of oxygen, but the oxygen carriers are decreased in amount either because the hemoglobin is diminished in concentration or is changed in character. (3) The stagnant form, in which the arterial blood is saturated with oxygen to capacity and the oxygen carriers are adequate in amount, but the difficulty is in the slow rate at which blood passes through the capillaries. Recently Peters and Van Slyke<sup>6</sup> have added a fourth form, the histotoxic, in which the cells themselves have difficulty in utilizing the available oxygen. Of course, in many diseases two or more forms of oxygen want may be combined. This division of oxygen want into various forms and degrees is of more than academic importance, because, as will be shown in a moment, a consideration of these facts will determine the rational application of oxygen therapy.

\*From the Heart Station and Department of Cardiovascular Research, Michael Reese Hospital.

Received for publication, November 10, 1933.

Presented by invitation at the American Congress of Physical Therapy, September 12, 1933, Chicago, Illinois.

What can oxygen therapy do? It is quite obvious that increasing the proportion of oxygen in the air which the patient inhales from one-fifth, normally present at sea level, to one-half of the total air breathed will increase the oxygen content in his alveoli, and therefore, the quantity of oxygen passing into the blood. The amount of oxygen that can go into physical solution in the blood is very small; practically all of it combines in a loose chemical form with the hemoglobin. Obviously, when the hemoglobin is saturated with oxygen very little more can be added. It is, therefore, self-evident that when the oxygen want is of the anemic, stagnant, or histotoxic forms no improvement from oxygen therapy may be expected. In carbon monoxide poisoning, oxygen and carbon monoxide can be viewed as competitors for hemoglobin, and increasing the available oxygen will drive off the carbon monoxide more rapidly. Oxygen therapy, therefore, may be of value in this condition.

Oxygen therapy is primarily of value when the arterial blood does not contain oxygen up to its capacity. But it may be used also where it is anticipated that the arterial blood will become unsaturated because the demands of the tissues for oxygen are expected to increase. This happens especially in postoperative states. In such conditions oxygen therapy might be considered as a prophylactic measure.

Oxygen therapy may not always raise the oxygen content of the arterial blood when the blood is not fully saturated with oxygen. Let us investigate this point further. Incomplete saturation of the arterial blood with oxygen may be due to several categories of causes. One cause is a short circuit of some of the venous blood which avoids air-containing alveoli. Some of the blood returning to the arteries remains in its "venous" state. Congenital heart disease, pneumonia, and atelectasis of the lungs may give rise to these shunts. It is obvious that adding more oxygen to the air-containing alveoli will have little effect on the oxygen content of the arterial blood since the oxygen cannot come in contact with the blood that has been short circuited. It is for this reason that occasional cases of pneumonia have been reported in which the arterial unsaturation is not changed by residence in a high oxygen atmosphere.<sup>4, 7, 8</sup>

In the other types of arterial unsaturation, oxygen therapy may be expected to increase the oxygen content of the arterial blood. In the type of anoxia due to an excessively rapid flow of blood through the lung capillaries, such as may occur in hyperthyroidism, disseminated pulmonary embolism, pneumonia and severe exercise, oxygen therapy will accelerate the rate at which oxygen can enter the blood and so compensate for the rapidity of the blood flow. In the type of anoxia due to rapid shallow breathing, oxygen therapy, best combined with  $\text{CO}_2$ , will break the vicious cycle of shallow breathing which the oxygen want itself aggravates. In the type of anoxia due to the presence of excessive fluid in the lung alveolar walls and spaces, which follows passive congestion, inflammation, infarction and the irritant effect of war gases and foreign bodies in the lung, oxygen therapy enhances the force which drives oxygen into the blood, and therefore, tends to overcome the increased resistance offered to the passage of oxygen. In the type of anoxia due to

Fig. 1.—A diagrammatic representation of the processes of internal and external respiration in various types of oxygen want, which shows the mechanism of action of oxygen therapy.

In the first diagram is shown the condition normally existing; at the left, the oxygen is being poured into the blood stream, represented by little boats from the lung reservoir (external respiration). These boats, as shown by the shaded areas, are filled almost to capacity. These boats move to the right (transportation). At the right, the oxygen is shown being poured out from the blood into the tissue cells which keep the "flame of life" burning vigorously (internal respiration). Increasing the level of oxygen in the lung reservoir to the dotted line, as occurs in oxygen therapy, has little effect on the oxygen content of the boats already fully loaded.

In the second diagram is shown the condition in histotoxic oxygen want. The only difference between this condition and the normal lies in the fact that the tissue cells cannot utilize their oxygen so readily. This is indicated by a constriction in the stem of the funnel leading to the "lamp." As a consequence the "flame of life" burns less vigorously, or may even snuff out. Raising the oxygen level in the lung reservoir by oxygen therapy, can have little effect in this condition since the boats are already almost full.

obstruction of the air passages or decrease in lung expansibility, oxygen therapy will tend to compensate for the poor aeration of the alveoli.

Cyanosis has been used by clinicians as an index of a low oxygen content in the arterial blood. The recent work of Lundsgaard and Van Slyke<sup>9</sup> in particular has shown that this is an imperfect index. Cyanosis is a color change due to the presence of a definite quantity of nonoxygen carrying (reduced) hemoglobin in the capillaries beneath the skin. The reduced hemoglobin in the capillary blood is roughly the average of that in the arterial and venous blood of the region. If the circulation be sluggish, either locally or throughout the body because of heart failure or shock, then the greater removal of oxygen by the tissues will increase the reduced hemoglobin in the capillary blood above normal. If, for this reason, the reduced hemoglobin of the capillaries exceeds 5 gm. per cent, cyanosis will appear. Cyanosis, therefore, will appear more readily than normal in polycythemic individuals, and less readily than normal in the anemic. It will occur more readily than normal when the subcutaneous capillaries are engorged. It is well known among clinicians that the ashen-gray color associated with general anemia or local pallor is more significant than the slight cyanosis of the florid polycythemic individual. It will be seen from this discussion that cyanosis does not necessarily mean anoxia of the anoxic form, and, therefore, without further evidence cannot be taken as a criterion for the use of oxygen therapy.

Recent observations have shown that oxygen therapy has certain side actions which may be of value, namely, it tends to slow the rate of respiration and the minute volume of air breathed. Accompanying this there is an increase in the alkali reserve and carbon dioxide content of the blood. There is a tendency for the heart to slow (except in auricular fibrillation), and there is a drop in temperature of from  $\frac{1}{2}$  to  $1^{\circ}$  C. in patients with pneumonia according to Boothby.<sup>10</sup> The effects on respiration and the heart have been shown to occur not only in patients with oxygen want but in normal subjects as well.<sup>3, 11</sup> The manner in

---

In the third diagram is shown the condition existing when the oxygen want is due to a sluggish circulation. The slow movement of blood is represented by a reduced number of boats. The delivery of oxygen to the tissue cells is decreased, hence their oxygen supply falls and again the "flame of life" decreases in intensity. Raising the oxygen level in the lung reservoir by oxygen therapy can have little effect in this condition since the boats are already almost full.

The fourth diagram represents the condition when the oxygen want is due to anemia. The small size of the boats represents the reduced capacity of the blood for carrying oxygen. The amount of oxygen reaching the tissue cells will, therefore, be decreased and the "flame" will again dwindle. Raising the oxygen level in the lung reservoir will not remedy the condition since the boats are already almost full.

The fifth diagram represents the condition when the oxygen want is due to carbon-monoxide poisoning. The reduced capacity of the blood for carrying oxygen, due to the formation of carbon-monoxide hemoglobin, is represented by the "stones" in the boats. Again the "flame of life" is lessened. Oxygen therapy, which raises the oxygen level in the lung reservoir, is of little avail except so far as it can displace carbon monoxide and dislodge some of the "stone ballast" in the boats.

The sixth diagram represents the condition when the oxygen want is due to a decreased oxygen content of the blood in the arteries, brought about by an admixture of "venous" blood. Some of the boats never pass by the lung reservoir, so that some of them are not fully laden when they reach the tissue cells. The oxygen delivery to the tissue cells is, therefore, decreased and the "flame of life" dwindles. Raising the level of oxygen in the lung reservoir will not remedy the condition because some of the partially empty boats are shunted and never reach the lung reservoir.

The last diagram shows the condition when the oxygen want is also due to a decreased oxygen content of the blood in the arteries. In this case, however, the incomplete filling of the boats is caused by an interference with the exchange of oxygen in the lungs. This is represented by a constriction at the mouth of the lung reservoir. The delivery of oxygen to the tissue cells is reduced because of the small loads carried by the boats and the "flame of life" dwindles. Obviously, increasing the level of oxygen in the lung reservoir by oxygen therapy will tend to overcome the constriction and fill the boats more completely. This is the condition in which oxygen therapy has possibilities of usefulness as discussed in the text.

which these side actions are produced is still unsolved. Whether it is some environmental factor in the oxygen chamber or a reflex set up by the increased oxygen content of the alveoli remains undetermined. However, both the slowing and diminution of respiration and the slowing of the heart are beneficial factors. The slowed heart beats more efficiently, and the load of work on the patient is decreased when respiratory effort is lessened. A similar action follows the lowering of body temperature. However, if these side actions were the only benefits to be derived from oxygen therapy they would hardly seem to warrant the trouble and expense involved in the use of oxygen.

From the foregoing analysis, it is clear that if oxygen therapy is to be used, it should be employed to increase the arterial oxygen saturation of those forms of arterial oxygen want where previous observations have shown that this can be accomplished. Oxygen therapy should be used where there is the possibility that the oxygen want contributes to the illness of the patient and where the likelihood exists that benefit will follow relief of the oxygen want. Therefore, oxygen therapy is most valuable in the acute and severe forms of oxygen want where the deleterious results of oxygen want rapidly outdistance bodily adaptations. There is less reason to use oxygen therapy in the chronic and mild forms of oxygen want where bodily adaptations have apparently compensated for the anoxia. In other words, oxygen therapy when used at all should be a temporary measure to alleviate acute, severe, generalized anoxic anoxia, where it is thought that restoring the arterial oxygen saturation will benefit the patient and check a downward clinical course. Oxygen therapy in no way acts on the underlying disease but only on the syndrome which follows anoxia. It should not be substituted for the ordinary armamentarium of the physician but be employed as an adjunct to the other forms of treatment. When given, oxygen therapy should be continuous until the desired effect is obtained, and should be maintained until the indications for its use no longer exist.

On this basis, oxygen therapy is especially valuable in postoperative conditions where rapid shallow breathing is present or where pneumonia seems imminent or has developed. It is, of course, valuable in other forms of pneumonia, but not in all cases. In cardiac patients it is valuable when there is evidence of severe passive congestion of the lungs and particularly in acute pulmonary edema. It can be of little use when these are absent and only the stagnant form of oxygen want exists. There is no evidence that it can benefit angina pectoris or long-standing cardiac edema unless these conditions are accompanied by severe pulmonary edema or stasis, except for the psychic effect on the patient which any elaborate therapeutic procedure can produce. Since it has no effect on the disease itself, oxygen therapy may fail even when the indications for its use are optimal and where relief of arterial oxygen unsaturation is attained.

The definite important place which oxygen therapy has in clinical practice will doubtless expand with further careful studies.

## THE DIETARY TREATMENT OF UNDERNUTRITION\*

### II. EFFECT OF THE GAIN IN WEIGHT ON CARBOHYDRATE TOLERANCE

MARSHALL S. BROWN, JR., M.D., AND ELAINE P. RALLI, M.D., NEW YORK, N. Y.

THE use of insulin to increase the weight of individuals who are underweight, seems to us unnecessary, except for the occasional patient who lacks the appetite to eat a high calorie diet. In the first paper of this series<sup>1</sup> we showed that on a high calorie diet the gain in weight over a period of six weeks was as great as the gains reported with the use of insulin,<sup>2,3</sup> except for one case reported by Nahum and Himwich.<sup>4</sup> There are certain disadvantages to the use of insulin. Aside from the inconvenience there is the possibility of hypoglycemia. Another effect, reported by Paul, Clark, and Gibson<sup>5</sup> is that following the withdrawal of insulin in nondiabetic patients, there occurred both hyperglycemia and glycosuria. This was observed in all six of their patients. On three of the patients glucose tolerance curves were done and showed a definitely diminished tolerance for carbohydrate. In one patient, followed for eight days after the discontinuance of insulin, the tolerance had still not returned to normal.

We are reporting the effect of a high calorie diet, which was accompanied by a definite gain of weight, on the carbohydrate tolerance of the six individuals observed. The subjects were third-year medical students. The diet contained approximately 430 gm. of carbohydrate, 175 gm. of protein, and 240 gm. of fat. The total calories ingested averaged about 4,500, although as high as 5,500 was taken for the last week by Cases 7 and 8. The carbohydrate tolerance was measured by glucose tolerance curves. These were done the morning before the diet was begun and the morning after the dietary period was finished. In each case 100 gm. of glucose was given by mouth.

During the period of the diet the students continued at their work and in no way curtailed their ordinary activities. The patients in Cases 7, 8, 9,

and 10 had always been underweight. The patients in Cases 11 and 12 had lost weight during the preceding year. The subjects were normal in all other respects.

### RESULTS AND DISCUSSION

Table I shows the weekly gain in weight in the 6 patients. The results are similar to those observed in the first group of patients.<sup>1</sup> The greatest gain in weight always occurred in the first week. The patients in Cases 11 and 12 were taking their final examinations during the last three weeks of the diet and did not eat the entire diet at this time. This is reflected in their weight charts.

TABLE I  
POUNDS GAINED WEEKLY ON DIET

| CASE    | WEEKS—POUNDS GAINED |      |      |      |     |      |     | TOTAL | WEEKS |

| 9    | 87                             | 152   | 154   | 116   | 78    | 17.25                   | 76                            | 105   | 133   | 117   | 81    |
| 10   | 80                             | 133   | 105   | 76    | 69    | 17.25                   | 80                            | 117   | 129   | 105   | 72    |
| 11   | 71                             | 86    | 125   | 105   | 86    | 15.0                    | 101                           | 121   | 104   |       |       |
| 12   | 76                             | 117   | 166   | 125   | 95    | 12.5                    | 75                            | 81    | 103   | 72    |       |

Table II shows the glucose tolerance curves on these subjects before and after the dietary period. These are all within normal limits. The average of the group is shown graphically in Chart 1. The second curve should be compared with the curve reported by Paul, Clark and Gibson<sup>5</sup> following the discontinuance of insulin. Individually the curves show that the height of the hyperglycemia after the dietary period was less in Cases 7, 9, 10, and 12, practically unchanged in 11. In the patient in Case 8 at the ½-, 1-, and 2-hour periods the hyperglycemia was greater than before the diet, although always within normal limits.

The students were weighed twice daily, before breakfast and after supper. Of the weight gained during the day, an average of 4 pounds was lost overnight. The true weight was that taken before breakfast. The constancy of this difference is shown graphically in Chart 2, which records the daily weights on Case 7. This is typical of the other five cases.

The ability of an individual to gain weight depends on his taking in more energy than he puts out. That this can be accomplished by means of a high calorie diet is shown in this group of subjects and in the group previously

Chart 1.

Chart 2.

reported.<sup>1</sup> The chief effect of insulin in undernutrition is its ability to stimulate the appetite. This makes it easier for the patient to eat a large amount of food. The gain in weight is due to the increased caloric intake. If the patient does not eat, insulin will not increase the weight. We had under

treatment in the hospital a patient twenty-three years of age to whom insulin was given 3 times daily before meals, ten units before breakfast, 15 before lunch, and 15 before supper. The patient had hypoglycemic reactions almost daily, but an increased appetite was not experienced. She refused to eat the entire diet and during a period of three weeks gained exactly 4 pounds.

|                     | 2 Unceda biscuits                       | 10   | 1    | 1   |
| Caloric value 4,574 |                                         | 423  | 177  | 246 |

When one considers that an impaired tolerance for carbohydrate may follow the use of insulin in nondiabetic individuals, and since a satisfactory gain of weight will follow the ingestion of a high calorie diet, it seems to us that the indiscriminate use of insulin in undernutrition is inadvisable.

## GAUGING THE DOSE OF INSULIN

B. Y. GLASSBERG, M.D., ST. LOUIS, MO.

*(From the Metabolic Service of the St. Louis County Hospital, Clayton, Mo., and the Medical Service of the Jewish Hospital, St. Louis)*

SINCE its introduction in 1922, insulin, one of the few specifics in medicine, has found wide acceptance. Unlike other specifics (morphine, quinine, the arsenicals, etc.), there is no approximately "standard dose" for insulin. Necessarily the insulin requirement varies with the individual patient, depending upon the indeterminate insulin secretion within his own body and the glucose equivalent of his diet. Hitherto achievement of adequate insulin dosage has been a tedious process. One of the standard usages defines that the patient be placed upon an almost starvation diet until the urine is sugar-free, that the food intake be gradually increased, and finally that he be given a number of units of insulin equal to one-half the amount of glucose, measured in grams, in the twenty-four-hour urine. As the diet is further increased insulin is further readjusted depending upon the urinary glucose content. If the patient be in diabetic coma, a standard plan calls for the administration of a definite number of units of insulin, usually between 20 and 40, each hour until the urine is sugar-free.

At best the methods are cumbersome. They fail to take into sufficient account the varying renal threshold for glucose.<sup>1</sup> Not infrequently the patient shows no glycosuria although the blood sugar is well above 250 mg. per cent. On the other hand an insulin reaction may be precipitated by failure to consider residual sugar in the bladder urine; or by failure to remember that glycosuria usually continues below the glycaemic level at which it began.

The ideal treatment of diabetes is that which insures a twenty-four-hour blood sugar curve analogous to that found in the nondiabetic. In addition to restoring the disturbed osmotic balance of the blood upset by the increase in blood sugar, maintenance of a normal blood sugar curve theoretically insures complete utilization of all available carbohydrate. It is common knowledge that the continuously aglycosuric diabetic with a normal blood sugar level develops a spontaneous increase in tolerance not shown by the intermittently glycosuric diabetic. Since bodily resistance is at least as great in the adequately controlled diabetic as in the nondiabetic, intercurrent infection and subsequent debility are rare.

With these considerations in mind I have found the following empiric method of gauging the insulin requirement of individual patients useful. It must be mentioned that the method has no logical basis in fact, unless it be that clinical experience has amply confirmed its complete safety and relative value. It is assumed that all of the glucose present in the body is equally distributed in all the tissues (regardless of the possible actuality); if the

blood of a 70 kg. patient contains 500 mg. per cent glucose (0.5 gm. per 100 c.c.), then the total glucose in the entire body may be assumed to be represented by the formula

$$\frac{70,000 \text{ (gm. body weight)} \times 0.5}{100} = 350 \text{ gm.}^2$$

Since the normal blood glucose (and body tissue glucose?) is roughly 100 mg. per cent (0.1 gm.), modification of the formula enables determination of the glucose present as excess:

$$\frac{70,000 \times 0.5 - 0.1}{100} = 280 \text{ gm. representing the amount of glucose which}$$

must be either burned, excreted, or synthesized into glycogen to restore a normal blood sugar level! A number of units of insulin equal to one-half the excess glucose in grams is assumed to be required to utilize the excess glucose; as a safety measure only four-fifths the estimated dose is given.

Hence in the hypothetical case here cited, 112 units  $\left(\frac{280}{2} \times \frac{4}{5}\right)$  of insulin may be given the patient.

The formula may be simplified for routine use as follows:

$$\frac{\text{Body weight in pounds}}{6} = \text{the number of units of insulin to be given}$$

for each 100 mg. per cent the blood sugar is above the normal glycemic level (100 mg. per cent). Applying this formula to the 154-pound (70 kg.) patient

with a blood sugar of 500 mg. per cent, it is evident that 104 units  $\left(\frac{154}{6} \times 4\right)$

of insulin will be required. As a matter of actual fact it has been my usual experience that such an amount of insulin will reduce the blood sugar only four-fifths (the safety factor) of the expected reduction; however, such a procedure enables avoidance of an insulin reaction. It has been found by experience as well as by unpublished studies that this change may usually be expected to take place within from two to four hours.

#### EXAMPLES

CASE 1.—L. H., female, aged fifty, weight 154 pounds. Blood sugar at time of injection of 70 units of insulin: 300 mg. per cent. Calculated blood sugar reduction: about 200 mg. per cent. Blood sugar two hours after insulin injection: 100 mg. per cent. Actual blood sugar reduction: 200 mg. per cent.

CASE 2.—F. E., female, aged fifty, weight 176 pounds. Blood sugar at time of injection of 120 units of insulin: 471 mg. per cent. Calculated reduction: about 300 mg. per cent. Blood sugar two hours after insulin injection: 131 mg. per cent. Actual reduction 340 mg. per cent.

CASE 3.—J. D., male, aged thirteen, weight 108 pounds. Blood sugar at time of injection of 120 units of insulin: 1,000 mg. per cent. Blood sugar two hours later: 550 mg. per cent. An additional 80 units of insulin was given. Calculated total reduction: about 820 mg. per cent. Blood sugar two hours after second insulin injection: 133 mg. per cent. Actual reduction: 867 mg. per cent. Some hours later the patient had to be given, at intervals, two small doses of adrenalin for the relief of clinical insulin shock. The following morning, sixteen hours after the last blood analysis, the blood sugar was 200 mg. per cent. The

importance of prompt and energetic treatment in diabetic coma is emphasized by the finding of a blood nonprotein nitrogen at this time of 42 mg. per cent; one may only conjecture how high it may have been during the intense acidosis accompanying the very high blood sugar. In another patient treated according to the same principles, the blood nonprotein nitrogen fell from 75 mg. per cent to 64 mg. per cent in ten hours and to 45 mg. per cent in three days; during the first ten hours the blood sugar fell from 900 mg. per cent to the normal level.

CASE 4.—L. M., female, aged fifty-three, profound coma, estimated weight: 75 or 80 pounds. Given 50 units of insulin on admission to the hospital. Blood sugar just before injection: 1,100 mg. per cent; blood nonprotein nitrogen: 119 mg. per cent. Complicating bronchopneumonia. As soon as the blood sugar report was obtained, the patient was given an additional 100 units of insulin. Calculated total reduction: about 830 mg. per cent. It was not possible to obtain another blood sugar determination until ten hours after the second insulin injection; at that time the blood sugar was 117 mg. per cent, the nonprotein nitrogen, 200 mg. per cent. Actual blood sugar reduction: 983 mg. per cent. Subsequent autopsy revealed an extensive nephrotic process in both kidneys as well as the bronchopneumonia noted at entry to the hospital.

*Comment:* The body weight formula described above (last formula) would have called for 160 units of insulin in Case 3 instead of the 200 actually given, and in Case 4 for 130 units instead of 150. Hence, it is felt that the margin of safety allowed by the revised formula is sufficiently great to permit its employment by the general practitioner. No generalized urticarial eruption or other anaphylactic manifestation was observed after the administration of these large amounts of insulin. Several years ago the former usually followed the administration of as much as 100 units of insulin.

*Note:* Patients are carefully watched for the appearance of symptoms of insulin shock; if glucose or orange juice cannot be given by mouth adrenalin hydrochloride (4 to 10 minims) hypodermically may be depended upon to relieve such symptoms without waiting for the report of blood sugar analysis. If necessary it may be followed by the intravenous or intracardiac injection of 50 per cent glucose (10 to 20 c.c.).

*Note:* In management of the postoperative diabetic the blood sugar is determined two hours after the patient's return from the operating room; the insulin requirement is calculated as above and further modified as food is allowed. By the use of this method we have successfully carried one patient with a previously uncontrolled diabetes through an immediate laparotomy for acute suppurative appendicitis. Neither acidosis nor insulin reactions marred a smooth postoperative course; no intravenous glucose was necessary at any time.

*Contraindications:* Patients with known myocardial damage. Since we give no insulin by preference, a very little if absolutely required, to such patients, untoward reactions have not been observed.

#### INSULIN DOSAGE IN ROUTINE DIABETIC MANAGEMENT

If diet alone proves insufficient to render the patient aglycosuric and the blood sugar normal two hours after a meal (preferably breakfast), the patient is placed in the hospital and immediately given the diet calculated as necessary for his maintenance upon discharge. From the blood sugar deter-

mined at entry the insulin required for the metabolism of the endogenous glucose is determined according to the formula described above. Further, it is assumed that one unit of insulin will metabolize four grams of exogenous glucose;<sup>3</sup> in the same manner as before only four-fifths the estimated dose is given to allow a safety factor; this amount may be easily ascertained by giving a number of units of insulin equal to one-fifth of the available glucose in the diet as measured in grams. Exogenous available glucose is calculated in the usual manner: 100 per cent of the carbohydrate plus 60 per cent (actually only 58 per cent) of the protein plus 10 per cent of the fat. The insulin is divided into one, two, or three doses depending upon the total requirement; the largest dose is given before breakfast, the smallest before lunch, and the intermediate dose before supper. Two hours after breakfast on the third day of this regime the blood sugar is again determined to permit further insulin regulation in preparation of the patient for discharge from the hospital; usually it is between 90 and 150 mg. per cent. If at the former level, insulin dosage is reduced; if higher than 150 mg. per cent, insulin dosage is readjusted on the basis of the endogenous glucose reflected in the blood sugar level. Ordinarily the insulin readjustment made at this time is sufficient to carry the patient for several weeks until mild insulin reactions indicate the need for further readjustment. This method permits the patient to receive intensive diabetic instruction in the hospital and return to his gainful occupation in from four to seven days.

Essentially the same plan is used in the after-care of the coma patient except that instead of basing the insulin dosage for the endogenous glucose on the blood sugar either on admission to the hospital or after its reduction by a massive dose of insulin, it is arbitrarily assumed that the endogenous glucose excess is represented by a blood sugar of 300 mg. per cent.

If for any reason the diet formula needs to be changed (for instance if the carbohydrate in the diet is to be increased in preparation for operation) insulin is readjusted according to the difference in the exogenous glucose supplied by the two diets.

#### EXAMPLES

CASE 5.—M. R., female, aged thirteen, weight 65 pounds. Blood sugar on admission to the hospital: 400 mg. per cent; insulin required for metabolism of the endogenous glucose as calculated: 33 units. Insulin required for metabolism of exogenous glucose supplied by diet of protein 40 gm., fat 60 gm., carbohydrate 100 gm., available glucose 138 gm.: 28 units. Total insulin requirement: 61 units. Sixty units of insulin, 30 before breakfast, 10 before lunch, and 20 before supper were administered. Two hours after breakfast on the second day of this regime the blood sugar was 181 mg. per cent. The insulin was increased by 20 units instead of by the calculated 10 units and there were questionable mild insulin reactions. On the fifth day of this regime the diet was changed to protein 40 gm., fat 75 gm., carbohydrate 80 gm., available glucose 112 gm., a decrease of 26 gm. of available glucose calling for a reduction of 8 units of insulin (when small amounts of insulin only are involved the customary four-fifths reduction is usually omitted). On the third day of the new regime during which she received 30 units of insulin before breakfast, 15 before lunch, and 25 before supper, the blood sugar two hours after breakfast was 154 mg. per cent. During the course of the next few days mild insulin reactions indicating a considerable increase in tolerance occurred and the insulin was further reduced to 25 units before breakfast, 10 before lunch and 20 before supper. Two months after discharge from the hospital this patient

had gained 20 pounds in weight and had been able to reduce the insulin to 20 units before breakfast, none before lunch and 15 before supper. Nine months after discharge she had gained an additional 10 pounds in weight and had further reduced the insulin to 15 units before breakfast and supper.

CASE 6.—C. R., female, aged eleven, weight 62 pounds. Admitted to the hospital in coma with a blood sugar of 666 mg. per cent. Treatment seemed ineffective and on the second hospital day I was asked to see the patient. She was semistuporous and quite weak; there was no fever or infection. At that time her blood sugar was 375 mg. per cent; insulin required for metabolism of the endogenous glucose: 27 units. I changed the diet of protein 35 gm., fat 50 gm., carbohydrate 80 gm., available glucose 106 gm. with 15 units of insulin before breakfast, 10 before lunch, and 15 before supper to protein 35 gm., fat 90 gm., carbohydrate 80 gm., available glucose 110 gm. Hence no change in the insulin required for metabolism of endogenous glucose was indicated. Uncertain of the "hangover" effect of certain questionable treatment earlier employed, the insulin was increased only 15 units, a little more than half of that calculated, so that the patient now received 20 units before breakfast, 15 before lunch and 20 before supper. On the third morning of this regime the blood sugar two hours after breakfast was 138 mg. per cent and on the seventh morning at the same time it was 125 mg. per cent.

CASE 7.—E. R., male, aged thirty-two, weight 128 pounds. Blood sugar on admission: 500 mg. per cent; calculated insulin requirement: 84 units. Actually he was given 100 units and suffered an insulin reaction so mild that only one ounce of orange juice was required to relieve it. Unfortunately it was not possible to obtain a blood sugar determination until twelve hours after the insulin administration; at that time it was 140 mg. per cent. Assuming that the blood sugar would rise to about 300 mg. per cent spontaneously, 42 units of insulin would be required for its control. The diet of protein 70 gm., fat 160 gm., carbohydrate 80 gm., available glucose 138 gm., required 28 units of insulin for metabolism of the exogenous glucose. The total insulin of 70 units was given, 30 units before breakfast, 15 before lunch and 25 before supper. (To simplify the problem two intermediate days with a relatively higher carbohydrate allowance have been omitted from the discussion.) On the third day of the regime outlined above the fasting blood sugar was 190 mg. per cent while two hours after breakfast it was 125 mg. per cent. The latter figure indicates that the patient was adequately controlled; to lower the fasting blood sugar it would have been necessary to give a midnight dose of insulin, a procedure which we dislike because of the inconvenience caused the patient. The patient was discharged from the hospital on the seventh day. Three months after discharge he had gained 15 pounds in weight and reduced his insulin by 5 units, to 30 before breakfast, 15 before lunch, and 20 before supper.

*Note:* In patients running an irregular fever less than the total optimal dose of insulin as calculated is given in order to minimize the possibility of an insulin reaction when the fever reaches a low point. However, in the case of an infection with a continued fever more insulin is usually required. I am unable to propose any definite rules for the diabetic management of such patients inasmuch as their insulin requirement varies from hour to hour.

*Contraindications:* As above mentioned. In patients with severe myocardial damage no insulin is given even though the blood sugar be as high as 300 mg. per cent. If acidosis supervenes insulin may be given cautiously in doses of 5 or 10 units at a time. Onset of anginal pain is considered an absolute contraindication to its further use.

#### SUMMARY AND CONCLUSIONS

1. The blood sugar of a diabetic patient in coma or of one presenting a high blood sugar may be safely and quickly reduced by giving a number of

units of insulin equal to one-sixth the body weight in pounds for each 100 mg. per cent the blood sugar is above the normal glycemic level (100 mg. per cent). If the physician cares to use larger immediate doses of insulin, carefully watching the patient at the time, he may give one unit of insulin per kilogram body weight for each 200 mg. per cent that it is desired to lower the blood sugar. While the ordinary supportive measures such as saline hypodermoclysis and cardiac stimulants are given according to indications, glucose, sodium lactate, etc., are not ordinarily employed in the treatment of the coma patient. The rapidity with which the symptoms may be controlled makes the latter medication superfluous.

2. Routine regulation of the diabetic patient presenting no complications may be quickly and safely attained by giving a number of units of insulin determined as above for the metabolism of the endogenous glucose plus a number of units of insulin equal to one-fifth of the available glucose in the diet as measured in grams. A blood sugar two hours after breakfast on the third day of this regime determines further insulin readjustment. This method permits intensive hospital diabetic instruction and yet allows return of the patient to his gainful occupation in from four to seven days.

3. Since the formula here presented is entirely theoretical in its conception and derives its only merit from satisfactory and apparently safe clinical experience, the fact must never be overlooked that it should be modified to the need of the individual patient as determined by that patient's clinical response. It should not be used in the treatment of patients with myocardial damage.

## SODIUM TAUROCHOLATE AND THE VIRULENCE OF HUMAN TUBERCLE BACILLI\*

H. J. CORPER, M.D., PH.D., MAURICE L. COHN, PH D., AND VYOLA J. HOPER, S.B.,  
DENVER, COLO.

DURING the course of studies attempting to disclose the factors accounting for the difference in gross colony characteristics of human and bovine tubercle bacilli noted on different culture mediums, particularly the striking difference on inspissated egg mediums (low spreading wrinkled form) and on potato mediums (elevated, heavy, limited form) as well as on inspissated whole blood mediums (thin veil-like spread growth<sup>1, 2</sup>), certain substances were incorporated in different nutrient mediums for the purpose of changing the physical-chemical properties of the medium, particularly to change the surface tension of the medium. Among those tried, one, sodium taurocholate in certain concentrations, produced decided changes in the nature of the resultant growth which led to a further study of the colonies and of the bacilli. Although our studies did not disclose the exact nature of the factors determining the characteristics of the gross growth on the various mediums, it did appear that by reducing the surface tension of these mediums to a common level there grew on these different mediums identical colonies of the so-called smooth-greasy type recorded as seen predominantly with virulent avian tubercle bacillus cultures on egg mediums.<sup>3, 4</sup>

The experiments were conducted with graded plantings from one milligram to one-millionth of a milligram and varying amounts of sodium taurocholate (Eastman Kodak Co.) were added to defibrinated cow blood, to egg white, to egg yolk, and to potato cylinder mediums which were then sterilized by inspissation or autoclaving as usual. All the mediums contained 3 per cent glycerol as is customary for growing human tubercle bacilli. With defibrinated cow blood, 1 per cent of sodium taurocholate inhibited the growth of small plantings; 2 per cent inhibited medium grade plantings; and 5 per cent inhibited moderately heavy plantings. With egg white, a poorer nutrient, the inhibition effects on growth were even more striking, and consequently the effect on the colonies was inappreciable. With inspissated egg yolk and potato cylinder mediums, inhibition was noted in the smaller plantings when the mediums contain 5 per cent sodium taurocholate but not when containing 2 per cent. Most striking, however, was the effect of the 5 per cent sodium taurocholate upon heavy plantings (one milligram or more per cubic centimeter seeding) in producing smooth, solitary, greasy appearing "avian-like" colonies on the egg yolk and potato cylinder mediums.

These colonies were, therefore, studied for their characteristics, regarding particularly the virulence of the bacilli and the permanency of the changes

\*From the Research Department, National Jewish Hospital.  
Received for publication, November 24, 1934.

produced. The former (the virulence) was studied by graded inoculation of fine suspensions into guinea pigs, a quantitative method of virulence determination, and the latter (culture characteristics) was studied by transfer back

Fig. 1.—The effect of sodium taurocholate in egg yolk and potato cylinder mediums on the nature of the growth of human tubercle bacilli. The four tubes on the left are inspissated egg yolk (1 mg. per c.c. plantings), the control being on the extreme left and in order the next three tubes contain 1, 2, and 5 per cent sodium taurocholate, respectively. The remaining tubes on the right (0.01 mg. per c.c. plantings) are potato cylinder medium, the first of this set being the control and the last three containing 1, 2, and 5 per cent sodium taurocholate. The strain of virulent human tubercle bacilli pictured is strain "Glueckson", and the period of incubation seven weeks. Note the characteristic culture type of growth for egg and potato, and the change to the smooth, moist appearing globular colonies in the presence of 5 per cent sodium taurocholate.

and forth for several generations on both the inspissated egg yolk medium and the potato cylinder mediums with and without the sodium taurocholate (5 per cent).

A number of different strains of human tubercle bacilli were studied; most of them that had been cultivated on the laboratory mediums proved readily adapted to the culture tests, but a few recently isolated strains could not be grown on the 5 per cent sodium taurocholate mediums. The property of producing the solitary "so-called" smooth, greasy appearing colony was readily attained with both virulent and avirulent human tubercle bacilli on one transfer to egg or potato mediums, containing 5 per cent sodium taurocholate, and return to their original culture form was also attained by one transfer to the egg yolk or potato medium not containing the 5 per cent sodium taurocholate. This is well illustrated in the accompanying picture. The effect of the change wrought in the cultures by the sodium taurocholate on the virulence was studied by comparing the quantitative general virulence

Fig. 2.—The immediate change to the characteristic growth for egg and potato after several transfers on egg or potato mediums containing 5 per cent sodium taurocholate when sub-cultured on egg yolk medium (left tube) or potato cylinder medium (right tube) without the sodium taurocholate. The strain of human tubercle bacilli is "Gluckson" and the incubation period four weeks.

of the taurocholate cultures with the ordinary cultures of the same strain, and using for this purpose both virulent and avirulent human tubercle bacilli.

The method of testing virulence, used for years in our laboratory for human and bovine bacilli, was based on the findings of one of us<sup>2</sup> from an extensive study of the effect upon the development of general tuberculosis in the guinea pig following various routes of infection. At that time it was found that the development of disease in the guinea pig differed little for practical purposes with the average strain of human or bovine bacilli, regardless of whether injected subcutaneously, intraperitoneally, or intravenously; and therefore, the subcutaneous method was chosen because of the ease of noting the development of disease by the enlargement of the local gland. The subcutaneous method has been used for general systemic virulence tests in guinea pigs and has proved of service in determining the virulence of human

and bovine tubercle bacilli with graded amounts of fine suspensions of these bacilli. The dilutions used are noted from Table I and duplicate tests (2 guinea pigs) were inoculated for each dilution being tested.

\*For a report on the Virulence of these two strains see: Corper, H. J., and Cohn. Maurice L.: The Viability and Virulence of Twelve Year Old Broth Cultures of Tubercle Bacilli Maintained at Incubator Temperature. *Am. Rev. Tuberc.* 28: 856, 1933.

†The result of examination of the guinea pigs at postmortem is recorded as + indicating a definite tuberculosis or 0 indicating the absence of macroscopic tuberculosis in any of the organs or tissues.

‡The bacilli used were taken from the third subculture on the indicated medium.

The results recorded in Table I indicate that although sodium taurocholate in 5 per cent concentration in inspissated egg yolk mediums (or potato cylinder medium, results not tabulated) causes an immediate change in the gross colony appearance to that of a smooth-greasy "avian-like" colony, but it does not enhance the virulence of avirulent human tubercle bacilli in spite of at least three continuous transfers on the taurocholate medium. A virulent strain of human tubercle bacilli would appear to have increased in virulence from the results obtained, but when analyzing these results they prove to be more apparent than real, in that a transfer back to a medium not containing taurocholate reveals the change to be rather one of temporary nature and not one of virulence increase. There are two factors which may contribute to this apparent change, one the increased concentration of the bacilli in the taurocholate colony, and the other the greater ease of preparing finer dispersed and more stable suspensions of the bacilli in the presence of the taurocholate.

In view of our findings with sodium taurocholate recorded above, and other observations not recorded here, we feel that the problem of correlation between rough colonies and avirulence, and smooth colonies and virulence for human and bovine tubercle bacilli merit further exhaustive investigation with careful control both as to virulence tests and the physical-chemical nature of the mediums. It would appear also that the characteristic of rough or smooth for human and bovine tubercle bacilli may represent changes dependent more or less upon the physical-chemical properties of the medium in close proximity to the individual colony.

## SUMMARY

1. Virulent and avirulent human tubercle bacilli grown on an inspissated egg yolk medium or on a potato cylinder medium containing 5 per cent sodium taurocholate following heavy plantings produce smooth-greasy appearing "avian-like" colony growths which can be changed by a single transplant on the same mediums not containing taurocholate.

2. Avirulent human tubercle bacilli grown through several generations on egg or potato nutrient mediums containing 5 per cent sodium taurocholate do not show an increased virulence for guinea pigs in spite of the temporary physical change in the gross colonies.

3. Virulent human tubercle bacilli grown on egg or potato nutrient mediums containing 5 per cent sodium taurocholate show a transient apparent increase in virulence for guinea pigs.

## VII. AUTONOMIC IMBALANCE IN ANIMALS\*

JOSEPH B. WOLFFE, M.D., PHILADELPHIA, PA.

DURING the last four years we have used several hundred animals in studying the qualitative and quantitative effects of drugs affecting the autonomic system (we use the term "autonomic system" to include the central and peripheral sympathetic and parasympathetic nerve fibers, as well as the individual metabolites affecting them). We were impressed with the striking variations in the reaction of animals to epinephrine, which is considered a typical sympathicotropic stimulant, and the reaction following the administration of Desympatone† (active principle of Tissue Extract 568), which, as we have shown, stimulates the parasympathetic system.<sup>2, 4, 5, 6, 7</sup>

We were able to subdivide our animals (mostly dogs) into three groups or classes.

*Group I.*—Animals which are very susceptible to epinephrine, and relatively insensitive to desympatone.

*Group II.*—Those showing reverse phenomena, being particularly susceptible to desympatone and relatively insensitive to epinephrine.

*Group III.*—Animals showing rather a marked susceptibility to the effects of both types of drugs. In our experience we have not found a dog which failed to respond to the administration of therapeutic doses of both substances, although it is conceivable that such animals might be encountered.

This marked variation in susceptibility was emphatically called to our attention when, during one working day, tests were made upon two nonpregnant dogs weighing approximately 10 kilograms each, and anesthetized with morphine and chlorotone. Fig. 1 shows the comparative effects of epinephrine and desympatone (Dog 301). This animal showed a slight reaction to desympatone, but was extremely sensitive to epinephrine. After administering 20 gamma ( $\frac{20}{1000}$  milligram) of epinephrine, a marked rise in blood pressure was produced (Fig. 1, A). Simultaneous electrocardiograms showed dropped ventricular beats. This occurred at the height of the blood pressure rise. It is usually accepted that epinephrine causes an increase in the cardiac rate. This animal definitely showed a normal auricular rate, but the ventricular rate was cut down markedly on account of the ventricular asystoles (Fig. 2, A). In this tracing, reading from left to right, one sees an auricular complex marked P; this is followed by QRS T-waves, which represent systole of the ventricles. The QRS complex is registered by very fine lines, requiring careful examination or the use of a magnifying glass for the untrained eye. Another normal P, QRS, T follows; then three P-waves representing three auricular systoles with

Received for publication, June 7, 1933.

†Different lots of tissue extract contain varying small amounts of histamine and choline compounds. Chemical studies are being made to remove them. The desirable clinical effects are attributed to "Desympatone," which is a distinct entity.

Fig. 1.—Showing effect of epinephrine and desympatone on Dog 301. This animal showed but slight reaction to desympatone, but was extremely sensitive to epinephrine.

only one ventricular response QRS, T; two normal cardiac cycles were again registered, followed once more by a ventricular standstill; this cardiac disturbance continued until it returned to its normal rhythm. The injection of

2 c.c. of tissue extract showed but a slight drop in blood pressure (Fig. 1, *B*); 4 c.c. of tissue extract also showed but a slight depressor effect (Fig. 1, *C*); 2 c.c. of tissue extract and 20 gamma of epinephrine brought about a marked rise in blood pressure (Fig. 1, *D*) and 4 c.c. of tissue extract still failed to

Fig. 2.—Normal electrocardiogram, Dog 301. *A*, Epinephrine produced numerous ventricular asystoles in this animal. *B* and *C*, Desympatone did not produce the characteristic effects upon the heart rate and T-waves in this animal. *D*, Desympatone administered with epinephrine did not influence the T-waves but prevented the ventricular asystoles seen in *A* when epinephrine alone was given. *E*, Desympatone from a different lot also failed to show the characteristic effects on this animal.

completely neutralize 10 gamma of epinephrine (Fig. 1, *E*). Taken after 2 and 4 c.c. of tissue extract respectively, the electrocardiograms (Fig. 2, *B* and *C*) did not show the characteristic effect upon the rate and T-waves. When the mixture of the two was administered (Fig. 2, *D*) tissue extract apparently prevented the blocking effect of epinephrine in this animal, but did not influence the T-wave. We have already shown in previous publications<sup>4, 5, 6</sup> that epineph-

rine and desympatone will affect the T-wave in opposite directions. In this animal the T-wave is not appreciably affected, since the T-wave in Lead 2 (Fig. 2), which we are continually registering, is very much like all the others seen in subsequent tracings.

FIG. 2.

Thinking that possibly the tissue extract solution was weak, we used 2 c.c. from a different lot, but the effect upon the kymogram and electrocardiogram was about the same (Figs. 1, F and 2, E).

Figs. 3 and 4 show the blood pressure and electrocardiographic effects produced in Dog 302, following the administration of the same solutions. This animal proved to be very susceptible to desympatone and relatively resistant to epinephrine. Ten gamma of epinephrine caused a primary rise and secondary drop in the blood pressure (Fig. 3, A). The rate is uninfluenced. A slight

FIG. 4.

change developed in the character of the T-wave and in the R-T interval (Fig. 4, A). One cubic centimeter of tissue extract, employing the same lot used on the first animal, caused a marked depressor effect (Fig. 3, E). The electrocardiogram (Fig. 4, B) showed a definite sino-auricular bradycardia and sinus arrhythmia. The T-waves are markedly depressed as compared with the high T-wave seen on the normal tracing. The rate has been cut down from 144 to

84. Smaller amounts 0.5 c.c. (Figs. 3, *C* and 4, *C*) and 0.25 c.c. of tissue extract (Figs. 3, *D* and 4, *D*) showed proportionate drops and corresponding electrocardiographic changes. An injection of 0.25 c.c. of tissue extract (Figs. 3, *E* and 4, *D*) and 0.1 c.c. (Figs. 3, *F* and 4, *E*) again showed proportionate effects. As small a volume as 0.05 c.c. tissue extract (Fig. 3, *G*) showed a slight fall in blood pressure.

The method of standardization of tissue extract depends upon its neutralizing the effect of epinephrine upon the blood pressure of a dog. Fig. 3 (*I, J, K, L*, and *M*) shows the effects produced when a constant volume of 0.25 c.c. of tissue extract is mixed with quantities of epinephrine ranging from 5 gamma to 50 gamma. With 5 to 25 gamma of epinephrine the depressor action predominates in this dog. With 35 gamma (Fig. 3, *L*), the fall and rise are equivalent; and with 50 gamma of epinephrine, the pressor effect prevails (Fig. 3, *K*). Therefore, tested on this dog, 1 c.c. of tissue extract apparently corresponds to 120 gamma of epinephrine or 120 units, while if the previous dog was used as a test animal, 1 c.c. of the same solution would be equivalent only to 2.5 units, approximately 50 times less than in Dog 302. The very definite effect of repeated doses of desympatone on the T-wave should be noted. In the earlier records the T-wave was markedly upright (as shown by Fig. 4, *A x 1*) and later on it became definitely diphasic (Fig. 4, *D x 2*) and then inverted (Fig. 4, *F x 3*). The P-wave in the normal tracing is extremely high (Fig. 4, *A Y 1*), much smaller in Fig. 4, *B Y 2*, and proportionately increases and decreases, depending upon the amount of desympatone administered. In these two animals the differences in the results are extremely striking; in the first animal (301) 4 c.c. of tissue extract failed to neutralize 10 gamma of epinephrine, while in Dog 302, 0.25 c.c. of the same solution completely neutralized 35 gamma of epinephrine. In an assay on Dog 301 alone this solution would appear to contain less than 2.5 units per cubic centimeter, while assays on Dog 302 would indicate the presence of 140 units per c.c. These extreme variations are seldom seen. We avoid such discrepancies by using a number of anesthetized atropinized animals in standardizing tissue extract. Marked variations in susceptibility of the components of the autonomic system have frequently produced apparent contradictions in the results obtained during our studies. We have learned to determine the relative susceptibility of test animals<sup>7</sup> in connection with research work on products of this type, as well as in such apparently simple studies as the U.S.P.X. bioassay of epinephrine solutions.<sup>3</sup>

The difference in tonus of the different components of the autonomic system should be kept in mind in studying drugs having a specific effect upon this system. Many of the contradictory results observed by different investigators may be due to these marked differences in the autonomic balance of the animals employed.<sup>7</sup> A subsequent paper will present methods of grouping animals according to their autonomic states.

At present it appears important to test out every animal first as to its reaction to epinephrine. As soon as the effect of epinephrine has worn off, the

response to desympatone should be recorded. These hormones are very quickly eliminated,<sup>7</sup> apparently without influencing the animal's response to other drugs.

#### CONCLUSION

In studying the quantitative effects of drugs acting upon the autonomic system, the susceptibility of the test animals should be determined relatively to standard solutions of epinephrine and desympatone (the active constituent of tissue extract). Such a procedure will eliminate many of the apparent discrepancies observed on unstandardized animals.

We wish to acknowledge, with thanks, the splendid assistance of Arnold Quici and Mabel E. Luccareni for their assistance in compiling the necessary data, and to Sharp and Dohme for supplies of Tissue Extract 568.

# INTRAVENOUS LETHAL DOSES OF AMYTAL IN THE DOG AND RABBIT AND A TABLE OF ANIMAL DOSAGES COMPILED FROM THE LITERATURE\*

HARALD G. O. HOLCK, B.S., PH.D., AND MUNIR A. KANÂN, M.D.,  
BEIRUT, LEBANON, SYRIA

IN COLLABORATION WITH HANS HOMMA, M.D.

RECENT barbiturate studies indicate that closer attention must be paid to various details and factors than has hitherto generally been done in establishing accurate dosages. Also in some cases results cannot well be interpreted because authors give incomplete information about what would appear to be essential points. Finally, comparisons are difficult owing to variations in criteria and toxicologic terminology.

Therefore, we wish (1) to present a summary of recent studies upon factors which need consideration, together with our own findings in regard to some of them, (2) to discuss the possibility of clarifying the toxicology terminology, (3) to present a mortality study in which we have tried to follow the discussed principles, and (4) to give a comparative dosage table in which, by our headlines, the topics are indicated about which we believe information is desirable for proper evaluation of the proposed values.

## SUMMARY OF RECENT STUDIES

*The Drug Used, Its Degree of Purity, the Form in Which Administered, the  $P_H$ .*—"Crystalline sodium amytal has a lower M.L.D. than the prepared solution of amytal,"<sup>20a</sup> partly due to difficulties of avoiding slight decomposition and of changing all amytal into sodium amytal. Even pure sodium amytal crystals may contain not more than 0.1 per cent unchanged amytal.<sup>2</sup> Our dog experiments with intravenous, prepared sodium amytal do not give values that differ from those of Swanson and Shonle,<sup>32</sup> who used pure sodium amytal. Slight lowering of the intended  $P_H$  of 9.5 to 9.8 causes separation of traces of amytal with loss of hypnotic power.<sup>32, 35</sup>

Perfect stability of sodium amytal solutions of up to five months is claimed;<sup>18, 21, 24</sup> others note a tendency to deterioration on standing.<sup>32, 35</sup> Our pooled remnants after two months needed filtering and about 25 per cent increase in anesthetic dosage. Hence, for research work we use solutions on the day of preparation only.

A 10 per cent concentration is about 50 per cent more anesthetic in the white rat than a 2 per cent one, hypodermically administered.<sup>21</sup> Also, intravenous saline injections into rats revive those fatally poisoned with concen-

\*From the Department of Pharmacology, School of Medicine and The Department of Pathology, School of Medicine, American University of Beirut.  
Received for publication, October 30, 1933.

trated solutions of sodium amytal.<sup>1</sup> On the other hand, rectal administration to dogs of 10 and 20 per cent solutions, respectively, give about similar results.<sup>32</sup>

As to *solvents*, ethyl glycol gives a more stable sodium amytal solution and dissolves amytal itself.<sup>21</sup> The pain factor necessitates rather dilute solutions for certain injections, and ethyl glycol must be studied further. A final acacia concentration of 10 per cent protects against circulatory effects (*Ibid.*).

In regard to *method of administration* and *rate of intravenous injection*, the rabbit shows an unusually large difference in lethal dosage between oral and other methods of administration.<sup>10</sup> Rabbits also survive operations better after oral than after subcutaneous administration.<sup>23</sup> And the lethal dose in this animal, and less so in the dog, declines very rapidly with increase in rapidity of intravenous administration.<sup>32</sup> Very rapid injection of but a few mls of even an animal's own blood may produce widespread disturbances, named "speed shock," with a possible early exitus.<sup>12</sup>

The total *number of animals*, and in mortality studies also the number in the fatal dose range, though not always available, would seem essential information for proper evaluation of any dosage. As to *sex*, adult female white rats are twice as susceptible to subcutaneous sodium amytal as are males, using deep anesthesia as a criterion,<sup>21</sup> but the two sexes are equally susceptible to nembutal.<sup>1</sup> Supposedly, the early *pregnancy* of 80 per cent of the amytal females is not changing the dose significantly. Rabbits do not show any sex difference when averaging many barbiturates after oral and intraperitoneal administrations;<sup>10</sup> the above nembutal report makes individual revision desirable. Very early *castration* makes the male need the male white rat dosage, whereas later castration reduces the dose needed;<sup>1</sup> however, the weekly production of anesthesia after early castration may have led to the development of some tolerance (*q. v.*). As to *age* and *size*, maturing male rats fall between adult males and females, and immature males and females give satisfactory results with female dosage.<sup>21</sup> In cats, 1.5 to 3.5 kg., the greater the weight, the slower the induction and the less the depth for the same dose per kilo, subcutaneously.<sup>20</sup> Our findings as to sex and size differences will be found under experimental data.

Regarding *external factors*, fluctuations in *room temperature* between 25° and 37° C. have not definitely influenced the M.L.D. of white rats in the fourteen series of experiments with intraperitoneal administration of 2 per cent solution of sodium amytal.<sup>32</sup> As to *excitement* and *fear* barbitate-treated rats, caged with a rabbit, though not attacked by it, remain awake considerably longer than the controls.<sup>13</sup> As much as 75 per cent dose differences with the same lot of white rats is "probably due to differences in strains of rats, seasonal changes, etc."<sup>26</sup> With groups of only 20 to 30 animals and no sex separation, any seasonal variation has yet to be established. Pending this, a direct comparison of amytal dosage of January with barbitate dosage of September<sup>31</sup> may be postponed. The possible influences of *diet*, *previous conditions of keeping animals*, and *barometric changes* are not reported upon. A *moist atmosphere* gives a more rapid recovery in monkeys treated with barbiturates than does a dry one.<sup>11</sup>

*Tolerance* of dog metabolism to amytal is not developed;<sup>4</sup> their example indicates intervals of about two weeks between administrations. Likewise, equally good anesthesia was obtained in fishes by repeating intraperitoneal injections up to five times, probably with ten-day intervals or more.<sup>15</sup> But repetition of injections within a few days of one another may necessitate twice the initial dose to produce anesthesia in the rat or death in the rabbit.<sup>9, 21</sup> Thus, probably, the immediately acquired tolerance is lost within a few weeks.

#### CLARIFICATION OF TOXICOLOGY TERMINOLOGY

(Comparisons of doses are further complicated because the toxicology terms do not mean the same to every investigator. Thus, the common term "minimum lethal dose" has variable meanings.<sup>33b</sup> It may mean a dose just sufficient to kill an occasional animal; e.g., Nielsen et al.<sup>22</sup> (1925) give increasing barbital doses to six cats, have the one on the highest dose die, and call that dose the M.L.D. Is it really justifiable to label any dose the M.L.D. from such an orientation experiment? Likewise Page and Coryllos<sup>24</sup> (1926) inject increasing amytal doses intravenously into nine dogs with fatal outcome to the one upon the highest dose, 95 mg. per kg.; they further state: "In one dose approximately 95-100 mg. per kilogram is fatal." No dose was tried between 75 and 95 mg. And the dosage is misprinted in a subsequent paper in which reference to the above gives the M.L.D. as 110 mg. per kg.<sup>31</sup> (Their Table VI.)

✓To Maloney, Fitch and Tatum<sup>19</sup> (1931) the M.L.D. causes death in 50 per cent of the animals, whereas Knoefel, Herwick and Loevenhart<sup>16</sup> (1930) define it as the smallest dose which kills over 50 per cent of the cases.

According to Swanson<sup>29</sup> (1932, a), "the M.L.D. is determined by requiring not less than 60 per cent (of the rats) to die on the same dose." Shonle, Keltch and Swanson<sup>26</sup> (1930) write that the M.L.D. is that which causes death of all or a majority of the animals on that dose. In the amytal series of Coutière<sup>3</sup> (1932) it seems to be the dose just large enough to kill every animal on that dose.

Similar divergence holds for the term "average fatal dose."<sup>7, 17, 32</sup>

To eliminate some less useful new barbiturates one may divide 350 rats among 16 barbiturates to get a rough idea of the effective and fatal dosage,<sup>22</sup> and even in a few cases use a rat a second time with at least a two-week interval.<sup>25</sup> But though there be a distinct advantage in using the values from one comprehensive piece of work for comparative studies, it does not seem quite justifiable to employ the values of the just-mentioned investigators for detailed comparison among the more important barbiturates, including the effects of varying percentages of the so-called M.L.D.<sup>30</sup> The number of animals is too small, the concentration is variable and nothing is said about a constant sex ratio. Even the revision of this comparative dosage,<sup>29b</sup> though using more animals, fails to consider the sex question and to keep a constant concentration.

✓In view of these difficulties of nomenclature we agree with Trevan<sup>33</sup> (1927) that it would be preferable to abolish the term "Minimum Lethal Dose" and to substitute a term that would always mean the same. He proposes the term

*median lethal dose* to designate a dose which will kill 50 per cent of all animals in question in a large group picked at random, and suggests the abbreviation L D 50 for it. L D 100 would be an unequivocal abbreviation for the certainly fatal dose. Proofs are given that the L D 50 is "in the neighborhood of doses with the minimum relative error of determination." Regarding the number of animals required in such determinations, mathematical evidence is furnished to show that about 30 is near the optimum, that significant increase in accuracy requires a great increase in number, and that "diminution of the group below 30 leads to a very rapidly increasing error." Or, as Trevan puts it: "The ratio of the cost of the test to the accuracy obtained reaches a minimum in the neighborhood of this group number." However, with larger numbers of animals, one may determine several points along the straight part of the mortality curve, usually between about L D 20 and L D 80, by splitting up this number into smaller groups, and get results "which will have only a slightly greater error than that which is obtained by injecting the whole group with the average lethal dose." The total number required for the determination of these points depends partly upon the slope of the characteristic and partly upon the accuracy desired. Trevan gives examples of this and adds emphatically that all "discrepant" results must be included. He<sup>33</sup> further writes (1932, a): "The ideal way is to get a set of groups symmetrically distributed around 50 per cent mortality with doses separated by intervals such that the difference of the logarithms is constant, the doses themselves, therefore, rising by equal proportions and not equal arithmetical differences. The L D 50 can be arrived at by drawing on squared paper the best straight line through the points obtained and determining where it cuts the line for 50 per cent mortality."

As to establishing the minimum effective dose, except when actual surgical operation is the aim, criteria vary so greatly both for the same and for other species that comparisons of results of different authors become quite difficult. Could not the Council or some other authoritative body suggest one or two criteria for each species of animals by which first to establish the M.E.D. in each case of new hypnotics, the stream of which as yet seems far from being stemmed?

#### EXPERIMENTAL DATA

The solution of sodium amytal was prepared in the usual manner, adding 8.85 mil. of N/2 pure sodium hydroxide solution to each gram of amytal with proper stirring, avoiding excessive heating, and with subsequent dilution by freshly glass-distilled, sterile water so as to make the concentration 10 per cent of sodium amytal. The solutions were always filtered, kept between 24° and 28° C. during use, and employed within six hours. On three occasions the  $P_H$  was checked and found to be within the range of 9.5 to 9.8.

Our original plan called for completion of all experiments during the warm months of October and November, but an outbreak of plague interrupted our animal supply and made it necessary to continue into December and January; however, the estimated L D 50 for the 109 dogs of the warmer months was only one milligram higher than that of the 71 of the colder ones, and in the case

of the rabbits a similar difference was found; hence, no important source of error was introduced by the change of season. So as to have more uniform temperature conditions during the actual experiments, the room was warmed and the temperature kept between 21° and 27° C. and the animals were kept well covered during the amytal action.

The short-haired varieties of rabbits were bought in the open market, and kept for at least ten days on a constant diet of wheat, carrots, fresh greens, and water. A total of 120 rabbits was used, 60 males and 60 nonpregnant females. Food, but not water was removed twenty hours before giving amytal.

The 180 dogs were delivered from the city pound, all breeds and mixtures, 90 males and 90 nonpregnant females, and kept on a mixed diet; as much

Chart 1.—Showing the weight ranges and uniformity of distribution of weights within each range; the size, dose, fate, method of administration and rate of injection for each and every animal (100 mg. per minute for dogs, 20 for rabbits); the increasing mortality with increasing doses, the very few delayed deaths and the higher mortality in the small dogs in the first four series.

bread and boiled meat as they would eat was given twenty-four hours before administering amytal; water was allowed all the time.

The determinations were completed in ten days upon the rabbits and in eleven days upon the dogs. On each day we tried to distribute the animals evenly among the doses.

The rabbit variation in weight was limited to the narrow range of between 1.40 and 1.95 kg. In the dogs, using only full-grown, apparently healthy animals, the weight range is that of the animals brought to us, with extremes of 2.7 and 23.4 kg. Chart 1 shows that the four series of 30 rabbits each, one for each dose, are very similar in their size distribution. In the six dog series the size distribution is sufficiently similar for biologic experiments.

Because rabbits are especially susceptible to very fast injections, we injected only 20 mg. of sodium amytal per minute into the marginal ear vein,

giving a minimum time of five minutes per rabbit. In case of the dogs the rate was 100 mg. per minute into the external saphenous vein. We are purposely giving our rate in terms of sodium amytal, so that later direct comparisons with pure sodium amytal mortalities may be more readily carried out.

In the rabbit the increase in dosage is 5 mg. of sodium amytal per kilogram for each new series. In the dogs, the dose increases in steps of 5 per cent (Logarithm 0.02119), so as to follow the latest suggestion by Trevan; this percentage increase seems to be very suitable for this type of medication. In either case the distribution around 50 per cent mortality was very satisfactory.

Chart 2.—Showing the percentage mortality of thirty animals on each of the indicated doses, the place where the best straight line fitting the points cuts the 50 per cent mortality line (L D 50) and the suitability of 5 per cent dose increases for intravenous amytal administration.

Our main results are shown in Charts 1 and 2 and in Tables I and II.

In view of the rather few mortality percentage points we have thought it best to draw the straight line that would best fit these, and thus to determine the L D 50 by seeing where this line would cut the 50 per cent mortality line. Because there seems to be a flattening in the middle values, one may try to use other types of curves; however, this will not appreciably alter the L D 50 value.

TABLE I

| All doses combined: 90 males 53 per cent mortality |             |               |             |
| 90 females 48 per cent mortality                   |             |               |             |
| 180 (total) 51 per cent mortality                  |             |               |             |

To the nearest milligram of amytal itself, the L D 50 for the rabbits with our rate of 20 mg. of sodium amytal per minute, intravenously, is 75 mg. per kg., and for the dogs, using 100 mg. per minute, 58 mg. per kg. Comparisons with the rabbit values of Knoefel<sup>16</sup> et al. (1930; 68 mg.) and of Coutière<sup>3</sup> (1932; 65 mg.) are impracticable because they did not use a fixed rate of injection, and employed much fewer animals (see Table III); Swanson and Shonle's<sup>32</sup> (1931) pure sodium amytal value of 86 mg. of amytal is based upon one breed of rabbits, a faster rate and lower concentration, and Barron's<sup>1</sup> (1933) recent report makes it highly necessary to consider the concentration even with intravenous medication of amytal. In case of the dog our value checks very well with that of Swanson and Shonle<sup>32</sup> (1931) for pure sodium amytal; they report an M.L.D. (over 60 per cent fatality) of 63 mg. of amytal per kg.; 63 mg. from our curve gives an L D 67; concentration and injection rate were the same in both cases. A tentative value for the L D 25 in the rabbit would be 68, and for the dog 52 mg. of amytal per kg. Similarly, a tentative value for the L D 75 in the rabbit is 81, and in the dog 65 mg. of amytal per kg. with our injection rates. Thus, in either case, an increase of 13 mg. of amytal per kg. increases the fatalities from 25 per cent to 75 per cent.

In case of the rabbits, 59 out of 62 (or 95 per cent) died within thirty minutes, and 3 (or 5 per cent) died in from one to four hours after completion of injection (Chart 1). In case of the 91 dog fatalities, 88 (97 per cent) succumbed within three minutes of finishing the injection, whereas the remaining 3 (3 per cent) died during the night. In most cases the acute death in the dogs was immediately preceded by a short period of marked hyperpnea. Both acute and subacute deaths have been included in the mortality percentages as being directly attributable to amytal. One dog had evidently recovered from amytal after twenty-four hours; however, it developed pneumonia and died on the third day; this we have classed as an amytal survival. Similarly, another one of our survivals had pneumonia, but made a perfect recovery. The rabbits were kept for at least ten days after the experiment; none died during this time nor did any show signs of being ill. The dogs were killed at varying intervals of time (from one to eleven days) after recovery, to be used in a study of any possible pathologic changes (see later discussion).

In regard to any possible sex difference in the rabbit, Table I shows the extreme variations one may expect when using only 15 animals in one group

(a) All doses are in amytal as such. Pure sodium amytal has been multiplied by the factor given by Swanson, 0.002, to give amytal. All rates in intravenous injections are in milligrams of sodium amytal.

(b) The species were: *Girella Nigricans*<sup>11</sup>; *Clinocottus Analis*<sup>11</sup>; *Apomatis Cyanellus* and *Caresius Auratus*, a few of each.

(15 males or 15 females). The reversal of the high mortality for the two sexes in the two middle groups with good similarity in the lowest and highest dosage, indicates that there was no clear-cut sex difference. Similarly, in the case of the dogs, one cannot draw any definite conclusion from Table II. In view of the fact that in both cases the combined survivals on all doses somewhat favor the females (16 per cent more females survive in case of the rabbits and 11 per cent in case of the dogs), and because we have had to increase the sodium amytal dose by 5 mg. above the initial 60 per kg. more frequently in the females than in the males to produce surgical anesthesia (see Table III), it may be worth while to study this possible sex difference upon a large number of animals.

Although the fatalities do not with certainty show any sex difference, Tables IV and V show that on the whole the female rabbits do not have their body temperatures nor their respiratory rates quite as much depressed as do the males, and that they recover faster than the males. Although it is not very satisfactory to speak of a standard deviation for a few animals, our values also indicate that some males recover as fast as the females, but most do not. We have only included the rabbits of the warmer months, because with temperatures of about 21° C. not only are the initial body temperatures and especially respiratory rates less, but the temperature falls are more marked and complicated by shivering. The standard deviations also bring out the enormous variations between recoveries in rabbits who have been given the same dose and are lying side by side. Furthermore, actually the lowest respiratory rate came in our readings at fifteen, thirty, or forty-five minutes, so respiration rates begin to recover at a time when body temperatures are still falling (low point usually at second hour reading). Of course, most of the early workers with amytal reported depressed respiration rates and body temperatures, but as far as we know none reported upon any sex differences.

| Intrap. | 50-70 | Anesthesia |
| Intrap. | 55    | Anesthesia |

- (c) Anesthesia is used to designate complete, deep or surgical anesthesia or narcosis. Sedative and light sleep doses have been omitted.
- (d) It seems probable but not certain that 10 per cent was used whenever no concentration is given for injected sodium amytal. This does not hold for oral administration in which probably extra water was given to the animal to rinse the stomach tube.
- (e) Courtesy of the Eli Lilly Company.

As to the possible effect of variability in size, a careful comparison between the mortality percentage of the heavier 50 per cent (from 1.62 to 1.94 kg.) and the lighter 50 per cent (from 1.41 to 1.62 kg.), and, similarly, between the 10 heaviest and the 10 lightest within each of the four rabbit series, shows clearly that within the given limits of weights the size was not important in regard to fatality upon any given dose. This may also be seen by looking at the

distribution of fatalities along the total range of weights for each of the four rabbit doses (Chart 1). On the other hand, in case of the dogs there is a higher mortality in the weight range of from 2.7 to 5.4 kg. (66 dogs) in the lower four dosages as compared with the range of either from 5.5 to 8.9 kg. (55 dogs), or 9.0 to 23.5 kg. (59 dogs). The curve for the group of smallest dogs starts at a much higher level and is much less steep than either of the other two (actual mortality percentages for each of the six doses is 50, 58, 60, 60, 55, and 82, respectively, for this group). The main reason for this difference would seem to be the fact that in the smallest dogs the total dose would have been given in a very much shorter time than in case of a large one; thus, the very fastest total time for any one dog was one and six-tenths, and the very slowest was fourteen and six-tenths minutes, whereas in case of the rabbits the values are five and three-tenths and eight and eight-tenths minutes, respectively. It is also possible that the very small dogs may be more of the lap or house-pet type, and therefore be slightly less vigorous. The difference is not due to any very unequal sex distribution within this group of small dogs (19 males and 25 females in the four lower groups).

To get an approximate idea of what the L D 50 would be in the dog in the absence of extreme body weight variations, we have examined mortality curves for the middle two-thirds of each series (total of 120 dogs; approximate weight range of from 4 to 13.6 kg.), for the exact weight range of from 4.5 to 13.5 kg. in each series (117 dogs), and for the exact range of from 5.0 to 12.5 kg. within each series (96 dogs with not less than 15 in any of the six

groups). The L D 50 determined from each of these curves is 59 mg. of amytal per kg. of dog, or only 1 mg. higher than that for the total weight range.

Ravdin, Drabkin, and Bothe<sup>25</sup> (1931) report that repeated injections of good doses of sodium amytal into the white rat had no detrimental effect upon the heart, liver, lung, and kidney as judged by microscopic examination of these organs. In order to see whether or not lethal dose ranges of intravenously given sodium amytal injured the kidney or liver, sections were made from a large number of our dogs and stained with hemotoxylin and eosin. The slides from those that died acutely and those that were killed from one to eleven days after having been given the drug were then compared with the tissues of 10 apparently normal dogs which were killed by shooting. Table V shows that our street dogs, though apparently healthy, do show a good deal of pathologic changes.

TABLE VI

SUMMARY OF PATHOLOGIC CHANGES IN THE KIDNEY AND LIVER IN NORMAL AND IN AMYTAL-TREATED DOGS

|                                           | NUMBER<br>OF | BOTH ORGANS<br>NORMAL | SLIGHT CHANGES<br>IN ONE OR BOTH | MORE SEVERE<br>CHANGES IN ONE OR<br>BOTH ORGANS |
|-------------------------------------------|--------------|-----------------------|----------------------------------|-------------------------------------------------|
| "Normal" dogs                             | 10           | 50%                   | 30%                              | 20%                                             |
| Acute amytal deaths                       | 51           | 33%                   | 50%                              | 17%                                             |
| Killed one to eleven<br>days after amytal | 55           | 33%                   | 50%                              | 17%                                             |

Dr. Homma reports: "The changes found in the liver were parenchymatous degeneration and fat infiltration and periportal round cell infiltration; in the kidneys, parenchymatous degeneration and interstitial round cell infiltration.

"All these changes, except the interstitial round cell infiltration in the kidney, which was found three times only among the dogs treated with amytal, were also found among the supposedly normal dogs. Also, no relationship between the changes and the dose of amytal given or the time after the administration could be established. So it must be concluded that the pathologic findings in the liver and kidney were not due to amytal."

#### SUMMARY

1. The introduction discusses the relative merits of the various factors which may modify amytal dosage and the desirability of clarifying the toxicology terminology by the adoption of the median lethal dose (L D 50) as a common criterion of fatality, and gives suggestions as to the manner of conducting mortality studies.

2. Ten per cent freshly prepared sodium amytal solution was injected intravenously at a rate of 20 mg. per minute of sodium amytal per kg. into each of 120 rabbits, equal sexes, from 1.4 to 2.0 kg., divided into four groups of thirty each, and using differences of 5 mg. of sodium amytal between the groups. From the best straight line that fits the four mortality percentage points, the L D 50 comes out to be 75 mg. of amytal itself per kg. of rabbit.

The value is not readily comparable with those of other reports, for others used lower concentrations and faster or variable rates of injection.

3. Similarly, the use of an intravenous rate of 100 mg. per kg. in 180 dogs, equal sexes, wide weight range (from 3 to 23 kg.), distributed among 6 groups of 30 dogs each, and with 5 per cent increases in dosage, gives an L D 50 of 58 mg. per kg. of amytal itself. This value agrees closely with the values reported by Swanson and Shonle<sup>32</sup> (1931) for a similar concentration and injection rate of pure sodium amytal.

4. Within the weight range of the rabbits, size played no rôle in the fatalities. In the dogs, the low range of from 2.7 to 5.4 kg. gave a higher mortality rate in each of the lower four dosages. However, by eliminating the extreme weights in various ways, the L D 50 in each case comes out 59 mg. per kg., or only 1 mg. higher than for the whole series.

5. No definite sex difference in regard to mortality is established, but a large scale study is suggested to test whether the female rabbit and dog may be a little more resistant than the male. In regard to body temperature and respiratory rate, the female rabbits were less depressed and on the whole recovered faster than the males.

6. No difference was found between mortalities in the warmer months of October and November as compared with the cooler months of December and January.

7. Microscopic examination of the liver and kidney with comparison of these tissues of supposedly normal dogs show that there is considerable pathologic change in our dogs and that no pathologic findings could be attributed to amytal.

8. Finally, a comparative dosage table for amytal has been compiled from the literature with addition of our own values and enough information added to make it possible for others better to judge the accuracy of each of the proposed dosages.

We are greatly indebted to Dr. William M. Shanklin for aid in preparing the tissues, and to Dean George H. Miller for helpful suggestions.

## THE VELOCITY FACTOR IN BLOOD TRANSFUSION

THOMAS K. RATHMELL, M.D., AND WALTER J. CROCKER, V.M.D.,  
PHILADELPHIA, PA.

SINCE the time of the Egyptian kings man has tried to alleviate the suffering of his fellow men by introducing the blood of a healthy individual into the body of one who is ill.<sup>1</sup> This therapeutic procedure has persisted throughout the ages and has passed periods of acclaim and disrepute. The rationale of its use and the technic of its administration have varied from time to time. Our knowledge of transfusions has accumulated during these years. Many investigations have been made and pertinent facts have been ascertained, but the problem of transfusion reactions remains unsolved.

In studying the responses to intravenous injections, Hirshfeld et al.<sup>2</sup> have described a definite clinical syndrome which they term *Speed Shock*. This is characterized by an acute onset following the injection of a substance intravenously and giving rise to salivation, vomiting, diarrhea, dyspnea, muscle atony or spasm coincident with changes in the blood and in the circulatory and respiratory systems resulting in a fall in blood pressure and respiratory distress. They were unable to elicit this syndrome when the injections were made slowly and point out the danger of giving intravenous medication rapidly, and suggest that posttransfusion reactions are due to a rapid injection of blood, especially where a syringe method is employed. They suggest that for clinical purposes a rate of 2 or 3 c.c. per minute should be the upper limit for amounts of over 100 c.c., and 1 c.c. per minute for smaller quantities.

We have studied transfusions from the clinical aspect, maintaining a standard technic and utilizing only whole blood. While we could not control all possible variables in the clinical procedure as well as one might do in a laboratory test, because the life of a patient always was involved, we have utilized all the ordinary methods available to the clinician to enable a proper interpretation of our results. We wished to determine if velocity was responsible for any of our transfusion reactions.

### TECHNIC

Throughout this study we have used the Drummond Apparatus. This machine is essentially one of the stopcock type, designed to overcome the inconvenience and risk of error encountered in the use of apparatus employing a similar type valve (Fig. 1).

In this apparatus, as shown, it will be noted that the stopcock, which has three outlets, is mounted on the forward end of the machine. This moves in unison with the rotation of the barrel upon the plug, which is fixed. All air is

\*From the Philadelphia General Hospital.

Received for publication, November 21, 1933.

displaced from the lumen by physiologic saline solution and during transfusion a constant hydrostatic saline pressure is maintained upon the syringe while the barrel is in the level position. The normal donor to recipient flow cannot be reversed because of mechanical locks, while at any stage of the transfusion saline may be drawn into the syringe and given to the recipient or the lock on the donor's side may be released, if the operator desires, and an infusion of saline given the donor. By no means are you able to aspirate the recipient's vein at any time. Volume is accurately recorded by a calibrated disc which turns one marking each time the 5 c.c. syringe is emptied into the recipient's vein. This apparatus enabled us to use whole blood without the

Fig. 1.

addition of citrate solution or any form of anticoagulant, and the ease of mechanical operation allowed us to give our entire attention to the reaction of the recipient.

All parts of the apparatus coming in contact with the blood were sterilized by boiling for twenty minutes. Other parts were immersed in alcohol or formalin solution for a like period. Our tubing was of an ordinary commercial type. We lubricated the steel piston with either sterile vaseline or a sterile citrated vaseline preparation and packed the open end of the syringe with the same material. This step in the preparation of the apparatus was demonstrated to us by Dr. John Noecker. It allows a thin film of grease to be spread over the inside of the glass syringe with each stroke of the piston and embodies the wax tube principle utilized by Kimpton Brown.<sup>10</sup> After

each transfusion we cleansed the apparatus with physiologic saline, hydrogen peroxide, and alcohol or ether.

We prefer that our donors always have a serologic examination, a typing, according to the Moss grouping,<sup>1</sup> and a cross-agglutination test with the recipient. We have found that the cross-agglutination test is never absolutely reliable unless observed for one hour. We know of no case in which we removed blood from a syphilitic donor.

A surgical technic was maintained in preparing the extremity for transfusion.<sup>12</sup> Tincture of iodine, 3½ per cent, and alcohol of 70 per cent strength were used on both anterior and posterior aspects of the area not covered by sterile drapes.

The pain incident to venipuncture was eliminated by a subcutaneous infiltration over the vessel to be tapped of a 1 per cent sterile novocaine solu-

Fig. 2.—Showing vein held by suture material with single knot at 1 for retaining needle passed through incision at 3 and the blood current controlled by untied suture at 2.

tion. This procedure enabled the introduction of needles as large as 16 gauge without discomfort to either donor or recipient. When it was necessary to expose a vessel in order to introduce a needle into its lumen, we used novocaine anesthesia, making a small incision in the skin and carrying it down to the areolar tissue. Blunt dissection with a mosquito hemostat was used to isolate the vein, and it was brought to the skin surface by passing two short pieces of fine catgut under it. Separation of the ties, as shown in Fig. 2, enabled us to maintain complete control of the blood flow through the exposed section of the vessel. After the transfusion was completed and the retention ties removed from the vein it returned to its normal position. Temporary oozing was controlled by skin sutures and a pressure dressing.

Five minutes before giving the recipient the transfusion we recorded his blood pressure, temperature, pulse, and respiration, secured a complete blood count and a Schilling hemogram. Blood pressure was again recorded within five minutes after the transfusion and at the expiration of one hour, at which

time another blood count and Schilling hemogram were made. Urinalyses were made before and within twelve to twenty-four hours after transfusion. Temperature, pulse, and respiration were recorded at one, two, four, and six hours after transfusion. The following day another blood count and Schilling hemogram were secured.

The recipient's vein was tapped first. The needle being inserted in the direction of flow of the blood current. The efficiency of the venipuncture was tested by allowing at least 5 c.c. of the blood to flow into the syringe to which the needle was attached and immediately reinjecting this volume into the recipient's vein, his tourniquet having been released after the tap. We maintained the patency of the needle by injecting 10 to 15 c.c. of warm physiologic saline, during which time the tourniquet on the donor's arm was tightened and his vein tapped, the needle being inserted against the blood current. Connection with the apparatus was then completed, and with the appearance of blood in the syringe, from which it displaced physiologic saline, we considered the transfusion as started. Our estimation of total transfusion time includes from this instant until we withdrew the needle from the recipient's vessel. This was recorded by a stop watch.

The tolerance of the recipient to the blood was estimated clinically by giving the first 150 c.c. with extreme caution. We consider this a method of testing compatibility of bloods which should be regarded equally as important as the cross-agglutination test, providing the operator is trained in the clinical recognition of reactions. We always informed the patients of what was being done, when practicable, and asked them to tell us instantly of any new sensation or pain which they might experience. The facies, carotid pulsation and finger nails were observed for signs of cyanosis, distressed or altered expression, loss of pulse volume or acute circulatory collapse with resultant respiratory distress and embarrassment. These signs have been found clinically an earlier indicator of transfusion reaction than the substernal oppression, headache, and vomiting which all textbooks list.

Our estimation of velocity is based upon the total blood volume in cubic centimeters transfused, divided by the total transfusion time expressed in seconds. It is meant to accurately show the speed of transfer,<sup>9</sup> and is reported as cubic centimeters transfused per second. Velocity of transfusion depends upon the dexterity of the operator in temporarily connecting the donor's and recipient's veins. It is also influenced by the caliber of the needles used in the transfusion, it being impossible to propel in the same period of time, a given volume of blood through a needle of small caliber, as compared to one of larger lumen, providing we assume the propelling force to be the same. We have not attempted to approach the maximum in transfusion velocity but have maintained a standardized rate of transfusion which delivers the whole blood to the recipient in as near its natural condition as may be attained with present knowledge.

The danger of sudden death during transfusion is often totally absent from the operator's mind if the laboratory studies are favorable for transfusion. We have always kept prepared and ready for instant use a hypodermic of adrenalin and one of atropine sulphate.

## DISCUSSION

These cases were assembled from the routine work in the wards of the Philadelphia General Hospital. Our cases were not selected nor have we given any consideration, in recording our findings, to the metabolic, toxic or morbid state of the individual patient. We have studied a group of 37 patients who were given 50 transfusions. Thirty-nine transfusions consisted in the transference of ordinary whole blood; ten were of the nonspecific-immuno type<sup>4</sup> and one was a citrated nonspecific-immuno transfusion.

Our interpretation of a posttransfusion reaction was based upon the study of a composite clinical picture in each case. We considered a reaction as having occurred if the patient showed a sudden change of facial expression; cyanosis; complained of acute pain; had a loss of vascular tone or respiratory distress; suffered a chill with an acute rise in temperature; displayed a marked decrease in the number of circulating R.B.C. per c.mm.; and an associated increase in the Schilling hemogram "multiple index"\* (left shift) of 75 multiples; it having been shown by careful study that these changes in the clinical picture were not due to pathology present before the transfusion and unrecognized. Available material from our study leads us to believe that an increase in the multiple index of 75 constitutes the hemography of a posttransfusion reaction.

Kordenat and Smithies<sup>11</sup> found that in successful transfusions the post-transfusion leucocyte count was two or four times greater than before transfusion. Drinker and Brittingham<sup>8</sup> considered a rise in temperature of 2.5° F. as a reaction to the transfusion of citrated blood. We feel that transfusion reactions will be best interpreted when the decision is made, not upon a single clinical or laboratory factor, but is decided after a thorough study of the composite clinical picture of the individual case.

A total of 20,275 c.c. of whole blood was handled in this study, an average of 404 c.c. per transfusion. We considered the factor of acute cardiac dilatation only when the patient obviously had right heart failure. Dehydration is often present with the anemia, and before compatible blood could cause acute distention of a heart not already overburdened, the many venous lakes and the expansile factor resident in the venous side of the circulation would have to be taxed enormously. Crile has shown according to Col. C. Gordon Watson that the work of the heart increases in geometric ratio to the volume of blood, which in our transfusions was small. During the World War it was customary to transfuse large volumes of blood, usually 700 to 1,000 c.c. Major L. Bruce Robertson, C.A.M.C.<sup>7</sup> states that these cases never showed cardiac dilatation.

\*The "multiple index" indicates the number of times that a given shift is greater than normal. It is obtained by multiplying the Schilling index by 16. The normal Schilling index is 1/16. The normal "multiple index" is 1. The Schilling index is the ratio of shift cells (M, J, and St, the inefficient neutrophiles) to Sg or segmenters, the efficient neutrophiles.

$$\frac{M}{O} + \frac{J}{O} + \frac{St}{4} \cdot \frac{Sg}{64} = \frac{4}{64} \text{ or } \frac{1}{16}$$

If the Schilling index of an ill individual is  $\frac{3}{4}$ ,  $\frac{M}{2} + \frac{J}{4} + 30$ :

$$\frac{Sg}{48} = \frac{36}{48} = \frac{3}{4}$$

the "multiple index" is  $\frac{3}{4} \times 16 = 12$ . The Schilling index shows that there are 3 inefficient to every 4 efficient neutrophiles and the "multiple index" shows that the shift is 12 times greater than normal, that the Schilling index of  $\frac{3}{4}$  contains twelve 16ths, or 12 multiples of the normal left shift. Crocker and Valentine: Hemography in Diagnosis, Prognosis, and Treatment, J. LAB. & CLIN. MED. 1934. (In press.)

Our studies showed that:

*Average Velocity* of transfusion of whole blood was 1.02 c.c. per second.

*Blood Pressure.*—

Five minutes after transfusion, 45 comparisons:

|                               |                     |
|-------------------------------|---------------------|
| Systolic, increased 30 times  | average 12.1 mm. Hg |
| decreased 13 times            | average 14.0 mm. Hg |
| unchanged 2 times             |                     |
| Diastolic, increased 24 times | average 13.2 mm. Hg |
| decreased 14 times            | average 9.6 mm. Hg  |
| unchanged 7 times             |                     |

One hour after transfusion, 38 comparisons:

|                               |                     |
|-------------------------------|---------------------|
| Systolic, increased 20 times  | average 15.0 mm. Hg |
| decreased 15 times            | average 19.1 mm. Hg |
| unchanged 3 times             |                     |
| Diastolic, increased 18 times | average 13.8 mm. Hg |
| decreased 15 times            | average 12.6 mm. Hg |
| unchanged 5 times             |                     |

*W.B.C. Count.*—

One hour after transfusion, 50 comparisons:

|                    |                         |
|--------------------|-------------------------|
| increased 20 times | average 3,671 per c.mm. |
| decreased 30 times | average 3,205 per c.mm. |

Twelve to twenty-four hours after transfusion, 31 comparisons:

|                    |                           |
|--------------------|---------------------------|
| increased 12 times | average 5,120.8 per c.mm. |
| decreased 19 times | average 6,551.5 per c.mm. |

*R.B.C. Count.*—

One hour after transfusion, 50 comparisons:

|                    |                           |
|--------------------|---------------------------|
| increased 48 times | average 389,875 per c.mm. |
| decreased 2 times  | average 712,500 per c.mm. |

Twelve to twenty-four hours after transfusion, 31 comparisons:

|                    |                             |
|--------------------|-----------------------------|
| increased 21 times | average 509,523.8 per c.mm. |
| decreased 10 times | average 429,500.0 per c.mm. |

*Temperature.*—

Comparative readings at one, two, four, and six hours after transfusion, 38 comparisons:

|                    |                 |
|--------------------|-----------------|
| increased 33 times | average 1.3° F. |
| decreased 5 times  | average 2.8° F. |

*Pulse.*—

Comparative readings at one, two, four, and six hours after transfusion, 38 comparisons:

|                    |                                            |
|--------------------|--------------------------------------------|
| increased 29 times | average 141 $\frac{2}{3}$ beats per minute |
| decreased 9 times  | average 34 $\frac{2}{3}$ beats per minute  |

*Urinalyses.*—

Showed no changes of significance.

*Schilling Hemogram.*—

One hour after transfusion, 45 comparisons, of multiple index:

|                    |                                      |
|--------------------|--------------------------------------|
| increased 27 times | average 17.1 multiples (left shift)  |
| decreased 19 times | average 67.0 multiples (right shift) |

Twelve to twenty-four hours after transfusion, 29 comparisons, of multiple index:

|                    |                                      |
|--------------------|--------------------------------------|
| increased 12 times | average 37.8 multiples (left shift)  |
| decreased 17 times | average 73.8 multiples (right shift) |

*Pathologic Report.*—

Ultimate deaths

22

Autopsies

15

In no instance was death attributable to any other cause than the patient's disease. We have personally checked the histologic specimens of the kidneys in each of the fifteen autopsies and failed to find Bordley's post-transfusion kidney in any case.<sup>6</sup>

From an analysis of the composite clinical picture of posttransfusion reactions in our series of 50 transfusions, we found but two that showed evidence of a reaction. One was of a delayed type and one was of an acute nature. These two reactions represented 4 per cent of the total transfusions. The delayed reaction was due to the use of a so-called universal donor, without a cross-agglutination test having been made. The acute reaction, which conformed in every detail to Hirshfeld's description of *Speed Shock*, was found on recross-agglutination of the donor and recipient to be due to a definite incompatibility of the bloods which had either been missed at the previous examination or the titer of the agglutinating sera had been raised by the reaction.

Our observations to date include a series of over 125 transfusions of whole blood utilizing a similar technic. Two additional reactions have been noticed with the syndrome of *Speed Shock* in each case, but we have found that errors in compatibility were responsible for the reactions. There is a preponderance of opinion in the recent transfusion literature which emphasizes the fact that transfusion reactions are due to errors in compatibility (Parr and Krischner,<sup>3</sup> Polayes and Lederer,<sup>2</sup> Bordley,<sup>6</sup> Kordenat and Smithies,<sup>11</sup> also McClure and Dunn<sup>13</sup>).

While it has been held for years that the proper way to transfer blood was slowly, we have found that when the blood is compatible and untreated by extraneous chemicals, it may be given to the recipient according to our technic, at an average velocity of 1 c.c. per second without becoming a factor in the clinical picture of a posttransfusion reaction. We feel that keeping the blood out of contact with the vascular endothelium, which is its natural environment, for a prolonged period of time is undesirable.

#### CONCLUSIONS

1. The Drummond apparatus for blood transfusion is dependable and the mechanical principles which it embodies facilitate the transfusion of whole blood.

2. Anesthesia with a 1 per cent novocaine solution, as used in this study, eliminates the pain incident to venipuncture and should have a wider use in transfusion work.

3. The Schilling hemogram may be utilized in the study of transfusion reactions.

4. The *Speed Shock* syndrome was not elicited in the transfusion of whole blood at an average velocity of 1 c.c. per second except in cases where an incompatibility was demonstrated.

5. The study of a composite clinical picture is a preferable method of interpreting posttransfusion reactions.

6. Further studies on the velocity of transfusion of compatible whole blood are desirable.

THE VALUE OF THE MONKEY FOR THE STUDY OF THE LAXATIVE  
ACTIVITY OF PHENOLPHTHALEIN, ESPECIALLY IN COMPAR-  
ING DIFFERENT SAMPLES OF THE DRUG\*

---

EDWARD F. WILLIAMS, JR., PH.D., E. WILLIAM ABRAMOWITZ, M.D.,  
AND JOHN A. KILLIAN, PH.D., NEW YORK, N. Y.

---

MILLIONS of doses of phenolphthalein are taken annually in the United States for the well-known laxative action which it produces. For this purpose two general types of phenolphthalein, white and yellow (the more impure form), are placed on the market by manufacturers. The yellow product induces a much more powerful action than the white. Also, there is a considerable variation in the activity of samples of phenolphthalein from different manufacturers. Up to the present time the laxative activity of a particular sample could be estimated only by the use of human subjects, under constant conditions. A method of assaying this activity by the use of the monkey has been developed in the work described here.

All reports of the action of phenolphthalein in the lower animals fail to describe a laxative or purgative action similar to that in man except after relatively huge doses, usually requiring repetition. Such effects have been recorded by Abel and Rowntree<sup>1</sup> in dogs, van der Willigen<sup>2</sup> in cats, and Fleig<sup>3</sup> in dogs and rabbits. Vámosy<sup>4</sup> obtained no laxative action in dogs after a dose of 5 gm. and Fühner<sup>5</sup> found the drug completely inactive in mice after 20 mg. were given. On the other hand Loewe and Lange<sup>6</sup> reported a softening of the

\*Received for publication, November 13, 1933.

feces of mice after moderate doses (17 mg. per kilogram body weight), but failed to characterize their observation with a convincing description.

Fleig<sup>3</sup> expressed the situation admirably in the following statement: "It is to be regretted that an action, so intense in the case of man, hardly develops at all in the case of the animal and consequently cannot be studied with all the scientific precision of experimental analysis. Perhaps experiments performed on the monkey would be more fruitful; it would be interesting to try this animal." During the twenty-five years following this recommendation, no record of any one's having tried it has come to our attention.

#### EXPERIMENTAL

The samples of white and yellow phenolphthalein used in the experiments recorded here were made by the same manufacturer. The white was of U.S.P. grade and the yellow fulfilled all U.S.P. requirements except those concerning color. The latter possessed a very light canary yellow color in the powdered dry state, but in alcoholic solution showed a brownish yellow color modified by a slight fluorescence.

A series of 14 young white rats, weighing from 35 to 190 gm. each, received doses up to as much as 600 mg. (weight of rat, 135 gm.) of white and 84 mg. (weight of rat, 105 gm.) of yellow. Of the more than 500 doses given, only 2 (100 and 300 mg. of white phenolphthalein, respectively) were followed by a demonstrable softening of the feces. In both cases the rats failed to respond to a second and larger dose, furnishing further evidence of the inconstancy of the laxative action of phenolphthalein in the lower mammals.

A series of 5 cats, weighing from 2.2 to 4.0 kg., were given massive (5 to 10 gm.) doses of both white and yellow phenolphthalein in suspension in water or milk by stomach tube. Only repeated doses proved effective.

A dog, weighing 18 kg., showed no laxative action after a dose of 10 gm. of yellow phenolphthalein.

At this point we decided to try monkeys, although Fleig's suggestion had escaped our attention. These animals (*Macacus rhesus*), weighing from 2.0 to 3.5 kg., were found to be most suitable for the study of the drug. They were maintained on a regular diet of milk and eggs twice daily and fruits and vegetables once a day. Bone meal, cod liver oil, and at times blood meal were mixed into their fruit meal.

Each dose of phenolphthalein was accurately weighed on an analytical balance and then was quantitatively deposited in the interior of a piece of banana and sealed in. On feeding the piece of banana the monkey was closely watched to ascertain whether he consumed the material entirely. More pieces of banana then were fed to insure complete ingestion of the dose. If the quantity was sufficient to produce laxative action the effect would be evident in any case within from three to twenty-two hours, but usually within from six to twelve hours. After such a dose the stools became formless and semifluid, or if the dose was much above the minimum they became actually fluid. The former type of action properly is termed laxative, the latter purgative. When a minimum active dose was given, the action was always laxative and consisted of only a single action or of 2 or 3 at the most.

In order to establish the minimum therapeutic dose, gradually increasing quantities of the drug were given, with intervals of 1 mg. for doses less than 10 mg. and of 2 mg. for larger doses. Between each successive trial at least three full days were allowed to intervene. Finally that level was reached, below which no action occurred and above which laxative action always took place. This point has been determined for white phenolphthalein in 9 monkeys and for yellow in 5, as shown in Table I.

TABLE I  
MINIMUM THERAPEUTIC DOSES OF WHITE AND YELLOW PHENOLPHTHALEIN FOR MONKEYS

| MONKEY  | WHITE<br>PHENOLPHTHALEIN   | YELLOW<br>PHENOLPHTHALEIN  | RATIO: $\frac{\text{WHITE}}{\text{YELLOW}}$ |
|---------|----------------------------|----------------------------|---------------------------------------------|
|         | mg. per kg. body<br>weight | mg. per kg. body<br>weight |                                             |
| 1       | 2.8                        | 0.8                        | 3.7                                         |
| 1       |                            | 0.7                        | 2.3                                         |
| 2       | 6.8                        | 3.0                        |                                             |
| 3       | 4.8                        |                            |                                             |
| 4       | 5.0                        | 0.9                        | 4.5                                         |
| 4       |                            | 1.3                        |                                             |
| 7       | 4.0                        |                            |                                             |
| 8       | 4.1                        | 1.5                        | 2.7                                         |
| 9       | 2.1                        |                            |                                             |
| 9       | 2.1                        |                            |                                             |
| 10      | 5.9                        |                            |                                             |
| 10      | 5.7                        |                            |                                             |
| 11      | 4.1                        | 0.6                        | 6.8                                         |
| Average | 4.4                        | 1.4                        | 3.3                                         |

It will be noticed that the dose for 4 monkeys was redetermined with practically no variation from the level first established. The minimum dose for different animals, however, varied quite widely, as does the dose for human subjects. In one instance (Monkey 11) there is even a wide deviation from the average ratio of the dose of white phenolphthalein to that of yellow. As is usual in the case of experiments with animals, therefore, dependence should be placed rather in results obtained with several subjects than in those from a single animal.

The average doses thus obtained show the sample of yellow phenolphthalein to be about 3 times as powerful in laxative action as the white. This figure corresponds closely with the relative effect of these samples in human subjects. Other samples of phenolphthalein also have been assayed by using these same monkeys, and the results again confirmed the experience obtained with human subjects.

The field remains open for physiologic studies of the action of phenolphthalein on monkeys, with results which may enlighten us further as to its action on man.

## THE FUNGICIDAL POWER OF PHENOL DERIVATIVES\*

### I. EFFECT OF INTRODUCING ALKYL GROUPS AND HALOGENS

GLENN J. WOODWARD, M.A., MILTON, ORE.

WITH LYLE B. KINGERY, M.D., AND ROGER J. WILLIAMS, PH.D.

**S**IGNIFICANT of the unsatisfactory status of the present therapy of tinea infection is the large number of remedies used in its treatment. Considering the increasing incidence of the disease, its marked tendency to recur, and the frequency with which it persists in spite of prolonged treatment, comparatively few investigators have interested themselves in this particular problem of therapy. Apparently the first to do so were Bokorny<sup>1</sup> in Germany and Schamberg and Kolmer<sup>2</sup> in this country. Others whose publications have appeared at intervals in this field are Myers and Thienes,<sup>3</sup> Kingery and Adkisson,<sup>4</sup> Osborne and Hitchcock,<sup>5</sup> Schamberg, Brown and Harkins,<sup>6</sup> Bonar and Dreyer,<sup>7</sup> Smyth and Smyth,<sup>8</sup> and Legge, Bonar and Templeton.<sup>9</sup> These studies indicated that such phenol derivatives as thymol and salicylic acid which have long been known for their clinical usefulness have a just claim to their popularity. They also indicated that there might be other phenol derivatives less irritating than thymol but more effective toward fungi.

In recent years numerous studies of the *germicidal* properties of alkyl phenol derivatives have been made. Included in these is the work of Laubenthal,<sup>10</sup> Johnson, Hodge and Lane,<sup>11</sup> Schaffer and Tilley,<sup>12</sup> Klarman and his collaborators,<sup>13</sup> Rettger, Plastridge and Valley,<sup>14</sup> Coulthard, Marshall and Pyman,<sup>15</sup> Read and Miller<sup>16</sup> and others.<sup>17, 18, 19, 20, 21</sup> Substitution of halogens in phenols has been studied by Koch,<sup>22</sup> Bechold and Ehrlich,<sup>23</sup> and Klarman and Von Wövern.<sup>24</sup>

The present work was done in an attempt to follow up the work of Kingery and Adkisson<sup>4</sup> and find, if possible, derivatives of phenol which might be used internally as therapeutic agents. As a first step it was thought desirable to learn the effects on fungicidal properties produced by the introduction of various types of groups into phenol.

*Test Organisms.*—The entire group of cultures used in this work was obtained through the kindness of Dr. Fred Weidman of the University of Penn-

\*From the Department of Chemistry, Oregon State College, Corvallis, and Department of Dermatology, University of Oregon Medical School, Portland, Ore.  
Received for publication, November 17, 1933.

sylvania Medical School. The group was composed of the following fourteen yeasts and molds, practically all of which are known to be of a pathogenic nature—*Monilia tropicalis*, *Sporotrichum*, *Cephalosporium*, *Microsporon fulvum*, *Trichophyton interdigitale*, *Blastomyces*, *Monilia candida*, *Monilia pinoyi*, *Monilia metalondinensis*, *Monilia macedoniensis*, *Penicillium brevicaulis*, *Cryptococcus histolyticus*, *Coccidioides immitis*, *Trichophyton purpureum*.

*Compounds Tested.*—Thirty-seven derivatives of phenol were tested with regard to their fungicidal power. Phenol, itself, was used as a basis for comparison. We are indebted to Dr. E. Klarmann of the Plaut Research Laboratory of Lehn and Fink for his kindness in furnishing samples of the four ethers of resorcinol listed in the table. A few of the compounds were prepared in this laboratory. Included in this group were 3, 5-diethyl phenol; 3, 5-dibutyl phenol, n-amyl salicylate; and 2, 4-dinitrophenol. The m-cresol and p-chlorophenol were purified before use. For purposes of comparison two other common fungicides, iodine and mercuric chloride, were also tested.

#### EXPERIMENTAL

*Method of Testing.*—The method used by Kingery and Adkisson<sup>4</sup> in their fungicidal tests has been followed with certain minor changes. Sabouraud's dextrose agar was used for the solid media. This was prepared by adding 10 gm. "Difco"-Bacto peptone, 40 gm. crude glucose, and 15 gm. agar to 1,000 c.c. tap water. After the media had been adjusted to a pH of 5.2 to 5.4, it was autoclaved for twenty minutes at fifteen pounds pressure. The liquid medium used was dextrose broth adjusted and prepared in the same manner with the omission of the agar. Stock cultures were grown on the solid media.

Culture tubes containing from 10 to 15 c.c. of broth were planted with a loopful of yeast from the stock tubes, thoroughly mixed and grown, seventy-two hours at 37.5° C. in case of the yeasts and longer at room temperature in case of the molds.

The compound, the fungicidal power of which was to be determined, was dissolved in water whenever possible and diluted to the desired concentration. In a few cases it was necessary to use dilute solutions of alcohol, glycerol, sodium carbonate or potassium hydroxide as solvents.

To 2 c.c. of the drug solution contained in a sterile test tube was added 1 c.c. of the broth suspension of the yeast or mold.

The mixture was then shaken and at the end of one minute, thirty minutes, and sixty minutes several loopfuls were transferred to separate sections of a plate of Sabouraud's dextrose agar. The plates had previously been divided into quarters by marking on the bottom of the Petri dishes with a wax pencil. The fourth quarter was used as a control. Transplants were made to this section from a tube containing 2 c.c. of sterile distilled water and 1 c.c. of yeast suspension.

The plate was then incubated for a period of time depending upon the organism being tested. The yeasts required seventy-two hours at 37.5° C. while it was found that the molds gave the best results when left at room temperature at least a week. All plates were left at room temperature for three weeks when final readings were taken.

All tests were made at room temperature which varied from 19° C. to 23° C.

*Choice of Three Organisms.*—Because of the large amount of work involved in the preparation of cultures it was found necessary to limit the number of organisms used.

Preliminary tests made with the entire group showed that three organisms, *Monilia tropicalis*, *Sporotrichum*, and *Cephalosporium*, were the most representative. *Monilia tropicalis* has the appearance of a typical yeast and shows vigorous growth in the incubator. *Sporotrichum* seems to lie between the yeasts and molds in form while *Cephalosporium* is more nearly a true mold. The latter two organisms grow quite vigorously at room temperature. All three show more than average resistance to the fungicidal agents tested: All compounds were tested against *M. tropicalis* which showed the highest resistance in all cases, while *Sporotrichum* and *Cephalosporium* were used as checks with all of the more effective compounds but not with the simpler phenols.

*Control of Environmental Factors.*—*Temperature.* Since in the case of bactericidal studies an increase in temperature has been reported to cause a marked increase in the germicidal strength of various drugs, a few tests were carried out to determine to what extent the working temperature should be controlled for satisfactory results in fungicidal studies.

An increase in temperature from 10° to 30° C. was found to increase the fungicidal ability of the drug slightly. However, the difference between the effect at 21° and that at 30° C. was small enough to make it seem unnecessary to take any special precautions to control the room temperature while making the tests.

*Solubility.*—The most troublesome factor which had to be contended with throughout the work was the near insolubility of a large number of the compounds. An effort was made in every case to obtain an aqueous solution of the drug to eliminate any possible fungicidal action of the solvent. However, it was found necessary in a few cases to use 10 per cent alcohol, 1 per cent sodium carbonate, 30 per cent glycerol, and 0.5 per cent potassium hydroxide solutions as solvents. None of these solvents themselves were found to kill the organisms under the conditions of our experiments.

It has been suggested that the insolubility of compounds may be closely connected with their ability as antiparasitic agents.<sup>20</sup> When a drug which is highly insoluble in water comes into contact with the lipoids of the cells in which it is more soluble, a rapid absorption of the drug by the cell is thought to result. All of the compounds which have been tested in this work and found to be highly toxic to yeast and molds are very slightly soluble in water. It was found that a water soluble, colloidal trade preparation of chlorothymol known as "elymocol" was not as effective a fungicidal agent as the crystalline chlorothymol.

While using 1 per cent sodium carbonate solution as a solvent, it was found that the fungicidal power of a compound dissolved in the carbonate solution was less than that of the same compound in an aqueous solution. Salicylic acid dissolved in water at a dilution of 1:1500 is more effective as

a fungicide than salicylic acid dissolved in 1 per cent sodium carbonate at a dilution of 1-500 or sodium salicylate dissolved in a 1-500 aqueous solution. On the other hand, thymol, carvacrol and chlorothymol are only slightly less effective in a sodium carbonate solution. Compounds with stronger acid properties are apparently more affected by being used in an alkaline medium than more weakly acidic substances.

*Hydrogen Ion Concentration.*—By use of a quinhydrone electrode the pH of the dextrose broth was found to be 5.3. The 1 per cent  $\text{Na}_2\text{CO}_3$  solution had a pH of about 9 as did also a mixture of 1 c.c. of broth and 2 c.c. of 1 per cent  $\text{Na}_2\text{CO}_3$  solution.

It has been indicated before that the sodium carbonate solution did not prevent the subsequent growth of the yeast and molds. It is evident, therefore, that a marked shift in the hydrogen ion concentration toward the basic end of the scale does not produce a fungicidal action.

*Results of Fungicidal Tests.*—Table I summarizes the results of the fungicidal tests made on the three organisms selected. The maximum dilution of each compound effective at thirty minutes and the phenol coefficient calculated by using the thirty-minute tests as a basis are given for each organism. The phenol coefficients were calculated by dividing the maximum effective dilution of a compound at thirty minutes by the maximum effective dilution of phenol at thirty minutes when using the same organism. Where not enough tests were made with a compound to make possible the determination of a definite coefficient, an approximate coefficient is indicated.

#### DISCUSSION

It may be seen from the table that certain structural features are necessary in a compound for it to possess high fungicidal power. The substitution of one or more alkyl groups on the benzene ring in phenols increases the fungicidal power, the resulting phenol coefficient depending upon the number of carbon atoms in the side chain. Compounds containing an alkyl group with six carbon atoms arranged in a straight chain have the highest coefficients as far as it is possible to tell from present results. The position in the ring occupied by the substituted alkyl groups makes no striking difference although the work has shown that the meta and para compounds are slightly stronger in fungicidal power.

Dialkyl compounds are stronger in fungicidal power than the corresponding monoalkyl compounds. One would anticipate that a dihexyl phenol would have a very high fungicidal ability except that its use is probably prevented by its insolubility. In the case of the dihydric phenols it has been shown that it matters not whether the alkyl group is substituted for a hydrogen atom of the benzene ring or a hydrogen atom of the hydroxyl group. The isomeric compounds, *n*-hexyl resorcinol and the *n*-hexyl ether of resorcinol, have coefficients which are nearly identical.

The indications are, from the five compounds studied, that the introduction of one or more nitro groups into phenols does not increase the fungicidal power materially.

± "Approximate"; insolubility of the drug made more accurate estimation impossible.

The substitution of halogen atoms in phenols increases their fungicidal ability several times. It is worth noting that both in the case of phenol and thymol, the introduction of a chlorine atom increases the fungicidal power the same amount, namely fourfold. A substituted iodine atom has a greater effect than a bromine atom which in turn produces a higher phenol coefficient than does a chlorine atom. The substitution of halogen atoms also decreases the solubility of the compounds. Again the position on the ring taken by the

substituted halogen atom has no marked effect upon the fungicidal power.

In contrast to the statement that the position occupied by substituted alkyl groups or halogen atoms is unimportant is the fact that a carboxyl group substituted in the ortho position has been shown to exert an effect more than twice as great as when substituted in the meta or para positions. The substitution of the carboxyl group in the ortho position increases the fungicidal power of phenol more than does a halogen atom or short alkyl side chain.

Of the phenol derivatives which have been studied n-hexyl resorcinol and the n-hexyl ether of resorcinol possess the highest fungicidal power followed closely by chlorothymol. All three should prove useful in the treatment of fungous skin infections and all are being subjected to clinical trial. The n-butyl, n-amyl and phenyl propyl ethers of resorcinol as well as 3,5-dibutyl phenol have exhibited sufficient fungicidal ability also to warrant further study. Thymol, carvacrol and salicylic acid are now being used as fungicides and have given fairly satisfactory results in the actual treatment of skin infections.

*Fungicidal Power Compared with Bactericidal Power.*—A close relationship between fungicidal and bactericidal power has been observed throughout this study of phenol derivatives. The highest dilution of phenol which will kill *M. tropicalis*, (1-75) is very nearly the same as the maximum dilution (1-80) which kills *B. typhosus*. The dihydric phenols, hydroquinone, resorcinol and catechol have coefficients of less than one on both bacteria (*B. typhosus* and *Staph. aureus*)<sup>13</sup> and fungous organisms (*M. tropicalis*). The coefficient (2.5) for p-cresol (*B. typhosus*) reported by Coulthard, Marshall and Pyman<sup>15</sup> compares with the coefficient of 2.5 obtained when using *M. tropicalis*. As the length of the side chain increases, in alkyl substituted phenols, however, the phenol coefficients increase but more rapidly if the tests are made with fungous organisms than when bacteria are used. Thus hexyl resorcinol has a coefficient of 200 with *M. tropicalis*, 154 with *Cephalosporium*, and 133 with *Sporotrichum*, all fungous organisms, while the commonly accepted coefficient for the same substance on *B. typhosus* is approximately 46. This difference may be due in part to the use of a different method of calculating the coefficients. An interesting comparison may be made between the results obtained by Klarmann<sup>13</sup> and those obtained in this work with the monoethers of resorcinol.

TABLE II

#### SUMMARY

1. The fungicidal powers of 37 derivatives of phenol and of two miscellaneous fungicides, iodine and mercuric chloride, have been determined by

using as test organisms *Monilia tropicalis*, *Cephalosporium*, and *Sporotrichum*. These organisms were selected after preliminary tests as being typical of a large group of pathogenic yeasts and molds.

2. The position taken by the substituted alkyl side chains and halogen atoms has been found in general to have little effect on the fungicidal power of phenols; on the other hand salicylic acid, a phenol derivative having a carboxyl group in the ortho position, is far superior as a fungicide to the isomeric meta- and para hydroxy benzoic acids.

3. It has been shown that there is a definite increase in the fungicidal power of the alkyl phenol derivatives with an increase in the number of carbon atoms of the side chain; that in dihydric phenols the substituted alkyl radical may take the place of a hydrogen atom of the benzene ring or of a hydrogen atom of the hydroxyl group without causing any significant variation in the fungicidal power.

4. The substitution of halogen atoms has been found to increase the fungicidal power from four to ten times; the fungicidal strength increasing from chlorine through bromine to iodine. The introduction of nitro groups into phenols does not increase the fungicidal power.

# LABORATORY METHODS

---

## OBSERVATIONS ON THE TECHNIC OF THE FRIEDMAN TEST FOR PREGNANCY\*

---

A. M. YOUNG, M.D., CLEVELAND, OHIO

---

IN A RECENT address Dr. T. B. Magath<sup>1</sup> editor of the *American Journal of Clinical Pathology*, made the following statement: "Although clinicians have scientifically studied the signs of pregnancy for more than 5,000 years, recently devised simple laboratory tests can detect pregnancy earlier and more accurately than any set of clinical observations yet perfected."

The first practical laboratory test for pregnancy was introduced in 1927 by Aschheim and Zondek.<sup>2</sup> It consists of six subcutaneous injections of urine twice daily for three days into five immature mice, followed by inspection of the animals' ovaries one hundred hours after the first injection. The presence of blood points and lutein tissue constitutes a positive reaction. Aschheim and Zondek reported a series of 1,400 tests with 98.5 per cent accuracy. The test has now been performed throughout the world in many thousand cases, and its reliability fully established. The material in the urine responsible for the reaction was called prolان and was considered to consist of two anterior pituitary hormones.

The hypophyseal principle was found by Zondek in the hypophysis, in certain extracts of other organs, in placental tissue, decidual tissue and perhaps most important of all in the urine of pregnant women. A small quantity (about one mouse unit) was found in the urine of nonpregnant females and as much as from 3,000 to 5,000 units in pregnant women. This observation led Aschheim and Zondek<sup>3</sup> to propose the demonstration of a large quantity of prolان in the urine as a test for pregnancy. Although there is some question as to the site of origin and nature of prolان, the evidence seems to favor the view that it is an anterior hypophyseal secretion and that because of the presence of the living placental tissue in the pregnant woman it is formed continuously in very large amounts and excreted in part in the urine.

The pregnancy test was the outcome of animal experiments by Zondek<sup>3</sup> in the study of ovarian function. These studies of Zondek in Germany and those of P. E. Smith<sup>4</sup> in this country in 1926 were the first to reveal that sexual maturity was controlled by the anterior hypophysis and that hormones from this body initiate follicle ripening, ovulation and luteinization.

---

\*From the Laboratory Department, Mount Sinai Hospital of Cleveland.  
Received for publication, October 21, 1933.

In 1929, Friedman<sup>3</sup> recommended the use of a single mature rabbit to replace the five immature mice of the Aschheim-Zondek test. In the rabbit there is no periodic ovulation or luteinization of follicles and these changes normally occur only after copulation, consequently the mature female rabbit isolated from the male for a period of several weeks is an ideal animal for demonstrating the effect of prolactin. In addition to the simplification of the pregnancy test by the use of one rabbit, the time required is shortened from one hundred hours to forty-eight hours. The technique suggested by Friedman<sup>3</sup> in 1931 consists in the intravenous injection of 4 c.c. of a voided specimen of urine (three times daily for two days), a total of 24 c.c., into a mature female rabbit previously isolated for at least three weeks. About forty-eight hours after the first injection the ovaries are examined at autopsy. In a positive test the ovaries are enlarged, and show a number of prominent hemorrhagic follicles. In a negative test the ovaries are white, and while ripe follicles 1 to 2 mm. in diameter may be seen these contain clear colorless fluid.

Since the original publication by Friedman<sup>3</sup> a large number of tests for pregnancy, using rabbits as the test animal, have been reported in this country<sup>6, 7</sup> confirming his results.

The results of the 350 tests performed at the Mount Sinai Hospital of Cleveland are shown in Table I.

The earliest positive test in this series was thirty-two days after the last menstrual period.

TABLE I

## SUMMARY OF 350 FRIEDMAN TESTS AT MOUNT SINAI HOSPITAL OF CLEVELAND

|                                               |                |
|-----------------------------------------------|----------------|
| Total tests                                   | 350            |
| True positives (uterine pregnancy)            | 92             |
| True positives                                |                |
| (intact ectopic pregnancy)                    | 2              |
| (hydatid mole)                                | 1              |
| False positives (tumors)                      | 1 + 2 in males |
| False positives (tuberculous oophoritis)      | 1              |
| True negatives                                | 131            |
| Not pregnant                                  | 69             |
| Delayed menses                                | 12             |
| Fibromyoma uterus                             | 10             |
| Acute pelvic inflammatory disease             | 1              |
| Chronic pelvic inflammatory disease           | 1              |
| Tuberculous pelvic peritonitis                | 10             |
| Carcinoma cervix                              | 7              |
| Ovarian cyst                                  | 4              |
| Subacute endometritis                         | 3              |
| Postpartum                                    | 2              |
| Menopause                                     | 2              |
| Ectopic pregnancy (no intact chorionic villi) | 2              |
| Polypoid endometrium                          | 1              |
| Hydatid mole (postoperative)                  | 1              |
| Carcinoma breast                              | 1              |
| Carcinoma ovary                               | 1              |
| Benign tumor of serotum                       | 1              |
| Sarcoma of uterus                             | 1              |
| Fibromyoma with sarcomatous change            | 1              |
| Male urine (200 c.c.)                         | 1              |
| False negatives                               | 1              |
| Doubtful (early tests of series)              | 5              |
| Experimental                                  | 114            |

The one false positive and the one false negative test will be discussed later. Tests were done in four cases of tubal pregnancy, two of which were positive and two negative. On microscopic examination of the fallopian tubes intact chorionic villi were present in both cases which were positive while in the negative cases the villi were degenerating or necrotic.

In the case of hydatid mole the preoperative specimen of urine gave a characteristic strongly positive reaction and a negative result was obtained on testing the urine twelve days postoperatively. In the cases of tumors other than hydatid mole three gave positive results and twenty-two gave negative results. Of the three positive tests one was a female with a clinical diagnosis of teratoma of the ovary and the other two tests were in the case of a male with a clinical diagnosis of teratoma of the testis. The urines from the cases of teratoma of the ovary and of the testis were obtained through the courtesy of Dr. D. Seecof of City Hospital, Cleveland. The negative tests included various types of benign and malignant genital tumors as shown in Table I.

#### OBSERVATIONS RELATING TO THE TECHNIC OF THE FRIEDMAN TEST

Many minor modifications of the technic of the Friedman test have already been reported in the literature.

*A. Selection of Animals.*—Of first importance is the selection of proper animals. Some workers have used animals from three to four months of age. Friedman<sup>6</sup> recommends the use of rabbits after bearing young for biologic assay, as these animals give the most constant response to a given dose of the hormone. For routine use, however, ordinary domestic female rabbits weighing from 2 to 4 kg. give satisfactory results.

As in other biologic tests the rabbits are found to vary considerably in their reaction to a given dose of hormone. In a series of 55 mature rabbits, each of which was injected with 10 c.c. of pooled urine from pregnant women, 49 gave characteristic positive reactions, 4 gave minimal or grossly doubtful reactions, and 2 were negative. One of the two negatively reacting rabbits gave a negative result on repeating the test with a 10 c.c. dose but a positive result on injecting 20 c.c. The other was not retested.

As stated above the rabbits must be isolated from male rabbits or other females for a period of three weeks before injection. Some workers have eliminated this period of isolation by preliminary laparotomy and selection of those animals that have obviously not experienced hypophyseal stimulation for several weeks, with ovaries showing ripe or nearly ripe follicles with clear fluid but no hemorrhagic areas or corpora lutea.

The importance of inspection of the ovaries before selection of the animals was emphasized by Wood<sup>9</sup> who states: "We attach much importance to the preliminary inspection of the ovaries as we feel that this gives us an ideal opportunity for correctly interpreting the actual changes brought about by the anterior pituitary hormone present in the urine. This procedure is in our judgment the best possible control of the test."

We have followed this suggestion in 178 tests and recommend its use as strongly as does Wood.

Fig. 2.

Fig. 3.

Fig. 2.—Photomicrograph. Low power. Rabbit ovary. Normal ripe follicle.

Fig. 3.—Photomicrograph. High power. Rabbit ovary. Normal ripe follicle, showing granulosa cells and theca.

Of the 178 rabbits in which preliminary inspection of the ovaries was done, three showed corpora hemorrhagica, seven showed corpora lutea, four showed old areas of hemorrhage, and seven were found to be pregnant. These findings show the necessity of isolating rabbits several weeks or more for the complete involution of corpora lutea before the animal is in a satisfactory condition for the test. In the case of the seven rabbits (recent purchases) which were found to be pregnant on preliminary inspection, the test would have had to be repeated as Friedman has shown that, during the pregnancy, the rabbit requires a larger amount of the hormone to produce corpora hemorrhagica than it does in the non-pregnant state.

Of the 3 rabbits showing corpora hemorrhagica, one had not been used previously and had been isolated for a period of three weeks, the other 2 had been positive about four weeks previously. Of the 7 rabbits showing corpora lutea, 4 were recent purchases, isolated about one week, the other 3 had been

positive from one to two months previously. Of the four rabbits showing old areas of hemorrhage one was recently purchased and isolated only several days, the other three had given positive results, from one to two and one-half months previously.

It will be noted from the above figures that the majority of corpora hemorrhagica and old areas of hemorrhage (the changes which would lead to false positive results) observed from three to ten weeks after hypophyseal stimulation occurred in animals which had been used previously and in which positive results were obtained. In our experience 4 out of 5 rabbits as purchased in the open market were satisfactory upon preliminary inspection for immediate use in the Friedman test. In those as purchased on the market and isolated for the prescribed period of three weeks only one showed a corpus hemorrhagicum and

Fig. 4.

Fig. 4.—Photomicrograph. High power. Rabbit ovary. Positive test of twenty-four hours' duration (early corpus hemorrhagicum).

Fig. 5.

Fig. 5.—Photomicrograph. Low power. Rabbit ovary. Positive test of forty-eight hours' duration (early corpus luteum).

might have given rise to a false positive result. The preliminary operation, therefore, is of particular value in animals previously giving positive results, the period of complete involution in these artificially produced corpora hemorrhagica being variable and in some instances requiring longer than three weeks (see Fig. 10 of subinvolved ovary).

All of the rabbits were isolated from other rabbits as soon as purchased and were kept in individual pens at all times.

**B. Anesthesia.**—The anesthetic generally employed for laparotomy has been ether, although the use of sodium barbital and avertin<sup>10</sup> and other anesthetics has been reported. In the series of tests reported here morphine sulphate was injected intravenously and found most satisfactory. While the majority of tests were done using a half grain of morphine for rabbits weighing from 2 to 3½ kg.

(the average size of the animals used in the test) doses as high as 2 gr. were employed in the early tests of this series. Within a few minutes after the injection of the morphine, the animal becomes drowsy and relaxed and is ready for operation. Rabbits anesthetized with morphine will show local reflexes with muscular contraction on sharp cutting and quick handling but no pain apparently. These reflexes can be minimized or even abolished if the movements of cutting and handling are deliberate. Rarely the larger animals are insufficiently anesthetized with a half grain of morphine, whereupon an additional quarter grain is given. The animals remain drowsy for several hours and at no time do they show any ill effects. The use of morphine intravenously has the additional advantage of making it possible to perform the laparotomy without an assistant and of being economical.

Fig. 6.—Photomicrograph. High power magnification of rabbit ovary. Luteinizing follicle showing proliferation of granulosa cells and of theca.

Fig. 7.—Photomicrograph. High power. Rabbit ovary. Corpus luteum of forty-eight hours' duration showing proliferation of capillaries.

*C. Urine for Injection.*—In order to avoid doubtful and false negative results, the urine to be tested must be a satisfactory specimen. The patient is instructed to restrict fluids the evening before the specimen to be tested is collected, to void before retiring and to promptly bring the first voided morning specimen to the laboratory. The urine should be of a specific gravity of 1.015 or more. The amount of urine injected intravenously by different workers has apparently varied more than any other single detail of the test. Friedman<sup>7</sup> first recommended a single dose of 5 c.c. Later<sup>7</sup> he recommended the use of 24 c.c. in six doses of 4 c.c. each. Other workers have used single doses of 10 c.c., 2 doses of 10 c.c. each at twenty-four-hour intervals, and still others have injected concentrates of the hormone obtained by alcohol precipitation. The tests in the first half of our series were done with a single injection of from 10 to 15 c.c. At present we regard 30 c.c. in two doses of 15 c.c. each as more advisable. The

doses are given four hours apart in order to avoid injury to the rabbits by a large amount of urine which is always somewhat toxic.

The use of a large amount of urine does not lead to false positive results, since as much as 100 c.c. of urine from nonpregnant women have been injected in divided doses and the equivalent of 200 c.c. of male urine concentrated by alcohol precipitation have been injected in a single dose without producing false positive results.

In a certain number of cases (3 per cent in this series), the urine on injection proves toxic and results in the death of the animal. The urines in this series which proved toxic were either turbid with bacteria or were obtained from patients who were receiving medication. The urine may be purified before injection into another rabbit by the method recommended by Zondek as follows: The hormone is precipitated by adding five volumes of 95 per cent alcohol to 60

Fig. 8.

Fig. 8.—Photomicrograph. Low power. Rabbit ovary. Positive test of seventy-two hours' duration (corpus luteum).

Fig. 9.

Fig. 9.—Photomicrograph. Low power. Rabbit ovary. Positive test showing follicles of eight days' and of twenty-four hours' duration. (Corpus luteum, corpus hemorrhagicum.)

c.c. of urine. The precipitate is collected by centrifuging in large tubes, and the supernatant fluid is discarded. The precipitate containing any anterior pituitary hormone present is dissolved in as small an amount of distilled water as possible and extracted by shaking for fifteen minutes with three volumes of ether to remove the toxic substances. Folliculin is also removed by the ether extraction. The ether washings are discarded and the excess ether removed from the solution by aeration. The solution is then made up to about 10 c.c. with distilled water and injected slowly in a single dose. The 60 c.c. volume is chosen to allow for loss of about one-half of the hormone in handling.

*D. Examination of Ovaries.*—While in general one hundred hours is the time interval allowed when using the immature mouse as the test animal, Zondek<sup>11</sup> has reported a method of shortening the time of the mouse test from one hundred

to seventy-two hours. The modification is as follows: A 30 c.c. sample of urine is extracted with three to four volumes of ether. The ether washings are discarded and 0.9 gm. of glucose is added to the urine residue. The usual injections are then given.

In the test using the rabbit, Friedman<sup>2</sup> recommends forty-eight hours, and this is the time interval which has been generally adopted. Normally after copulation, twelve hours are required for the development of corpora hemorrhagica in the rabbit's ovary.

In a negative test the ovaries are white, and while numerous ripe follicles may be seen, there are no areas of hemorrhage present. In a positive test at forty-eight hours the ovaries are large, and show a number of hemorrhagic follicles which are easily recognizable grossly. Microscopically not only is hemorrhage in the follicles striking but there are also a number of apparently recently proliferated capillaries and the presence of one or more layers of maturing lutein cells.

The gross and microscopic examination of the ovaries (see Figs. 1 to 9 incl.) removed at intervals of from one to thirteen days after injection of urine from a

Fig. 10.—Gross photograph. Natural size. Rabbit ovary. Subinvolution of ovary (twenty-eight days after injection of urine of pregnant woman).

pregnant woman show important changes in the development of corpora lutea from the ripe follicles. At the end of twenty-four hours some of the follicles show a small central area of hemorrhage and lutein cells one or more layers in thickness apparently developing from the granulosa cells and from those of the theca interna. There is also visible in some of the follicles evidence of proliferation of new capillaries. It is probable that the hemorrhage in the corpus hemorrhagicum is due not to rupture of the follicle at ovulation but to bleeding from capillaries proliferating to maintain the developing corpus luteum. This view is supported by the fact pointed out by Friedman<sup>2</sup> that corpora hemorrhagica and corpora lutea may be formed whether or not ovulation occurs. In addition to maintaining the corpus luteum newly developed capillaries share in the organization of the follicular hemorrhage. At the end of forty-eight hours some of the follicles show larger areas of hemorrhage and a thickened collar of lutein cells, and quite a number of others show changes characteristic of the twenty-four-hour reaction. At the end of seventy-two hours the follicles show, in addition to more lutein tissue, well-developed evidence of organization of the central hemorrhage. By the fifth day the process is quite distinctive grossly, and at the end of a week the corpora lutea are prominent and unmistakable. Ovaries at five- and

eight-day intervals show follicles which grossly and microscopically can be dated as fully developed one-, two-, three-, five-, and eight-day reactions, indicating that the stimulus of the hormone is exerted continuously for about eight days.

Sections stained with Scharlach R. show a scanty deposit of lipoid globules in the lutein cells as early as twenty-four hours and increasing amounts of lipoid in the older lutein cells. Those of three and five days show abundant globules.

The majority of workers have accepted gross inspection of the ovaries as sufficiently characteristic for a final diagnosis in the test for pregnancy. While in the vast majority of instances we have found it satisfactory, our one false positive reaction would have been avoided by microscopic examination. This animal was injected with urine from a case of extensive tuberculous salpingitis and oophoritis, and forty-eight hours later showed hemorrhagic follicles. The test was repeated in two separate rabbits, both of which showed similar hemorrhagic follicles in the ovary which were grossly indistinguishable from corpora hemorrhagica. Microscopic examination, however, showed that there were degenerative and necrotic changes in the wall with hemorrhage into the follicles but no evidence of lutein tissue formation.

After surgical removal of the affected ovary and fallopian tubes of the patient, the Friedman test was negative on repeated trials.

These findings were further controlled by the injection of urine from five cases of advanced pelvic tuberculosis which we obtained from the Cleveland City Hospital through the courtesy of Dr. S. E. Wolpaw. All of these rabbits gave negative results. In 42 tests subsequent to this error all positive tests were controlled by removing one ovary at laparotomy and examining it microscopically for lutein tissue after frozen section. These operated animals may be used for a second Friedman test in about four weeks.

The one false negative test was obtained in the first half of this series when a single dose of 15 c.c. of urine was used. The specimen of urine had a specific gravity of 1.014. On repeating the test three weeks later, using the same rabbit and 15 c.c. of urine with a specific gravity of 1.028, a positive result was obtained.

Some workers have retested the animals giving negative results in cases for diagnosis with known positive urine. In the light of the variable reaction capacity of the animals this method of control is certainly indicated especially when less than 30 c.c. of urine is injected. In the latter part of our series 29 negative tests were controlled by injection of positive urine and this control of negative tests is now a routine procedure.

Since freshly voided urine from a known case of pregnancy is not always available for injection, the majority of the controls on negative tests in our series were done with concentrated urine. The concentration may be carried out as described above for detoxifying urine. For concentrating large amounts of urine the original procedure has been modified in order to reduce the amount of reagents required. The method is as follows: 500 c.c. of 95 per cent alcohol are added to 1,000 c.c. of pregnancy urine in a shallow pan and the mixture evaporated to dryness by fanning (in a hood). The sediment is taken up in

200 c.c. of 60 per cent alcohol and shaken vigorously in a shaking machine for one-half hour. The material is then filtered, the residue discarded and the hormone is precipitated from the filtrate by the addition of five volumes of 95 per cent alcohol and allowed to stand in the ice box overnight for complete precipitation. The supernatant fluid is discarded and the precipitate is dissolved in as small an amount of distilled water as possible (about 50 c.c.). This solution is extracted with three volumes of ether in order to remove the folliculin. The ether washings are discarded and the solution is aerated to remove the excess ether. An amount of the material equivalent to 40 c.c. of the original specimen is distributed into small tubes, each tube to be used as a positive control for negative tests. This measured concentrate is again precipitated with five volumes of alcohol and stored under alcohol in the ice box ready for use. (The amount equivalent to 40 c.c. of urine was selected in order to allow for some loss of the active principle in handling.) Before a lot of the concentrate is used for controlling negative tests a sample of it is injected into a suitable rabbit to determine its potency. Before the injection into a rabbit the alcohol is poured off and the sediment is taken up in a few cubic centimeters of physiologic saline solution.

#### RECOMMENDED PROCEDURES FOR THE FRIEDMAN TEST

1. Selection of ordinary mature domestic female rabbits weighing from 2 to 4 kg.
2. Isolation of the animals in individual cages.
3. Use of morphine sulphate intravenously as an anesthetic.
4. Preliminary laparotomy and inspection of ovaries with selection of animals with ripe or nearly ripe follicles but no corpora hemorrhagica or corpora lutea.
5. Injection intravenously of 15 c.c. of clear, filtered, first morning specimen of urine, warmed to body temperature, of a specific gravity of 1.015 or higher. This dose is repeated in about four hours.
6. Forty-eight hours after the first injection the wound is opened and the ovaries are reinspected. If the ovaries grossly appear positive, one ovary is removed and examined microscopically by frozen section. The presence of lutein tissue in the wall of one or more follicles associated with more or less hemorrhage into the follicle constitutes an undoubtedly positive reaction.
7. If the ovaries show no corpora hemorrhagica the wound is closed and the rabbit injected with 15 c.c. of known positive urine or concentrated urine as described above. A tentative report of a negative test is given. Forty-eight hours after the injection of the positive control urine the wound is opened and the ovaries are reinspected. If the ovaries now show corpora hemorrhagica and lutein tissue is observed microscopically, the final report of a negative test with the urine for diagnosis is given.

If facilities are not available for making frozen sections, a reinspection of the ovaries on the fifth or sixth day after injection will show sufficient lutein tissue grossly to make an undoubtedly positive diagnosis possible.

## AN IMPROVED ELECTRODE FOR THE MEASUREMENT OF POTENTIALS ON THE HUMAN BODY\*

T. W. FORBES, PH.D., NEW YORK, N. Y.

IN AN attempt to map the electrical potentials of the various parts of the body in connection with studies of the relationship of such potential differences to metabolism, it was necessary to use a large number of relatively non-polarizable electrodes. Such an electrode has been described by Alvarez, Freedlander, and Clark<sup>1</sup> and used by Purdy and Sheard<sup>2</sup> in connection with studies of metabolism. Our experience with the Alvarez electrode led us to attempt to eliminate the difficulties which we experienced: clumsiness due to the comparatively large size of the "H" tube; frequent cracking of the cross member of the tube, especially when this electrode is used with noncooperative psychopathic patients; the variation of conductivity due to changes in the amount of moisture in the gauze wicks; and the change of resistance and potential arising from the loosening of the copper wire embedded in stiff copper amalgam.

Our improved electrode, which is drawn to scale in Fig. 1, consists essentially of an outer tube of one inch diameter, which functions in the same manner as the wick-bearing arm of the Alvarez "H" tube, and an inner tube  $\frac{1}{4}$  inch in diameter, which functions essentially in the manner of the second side of the "H" tube. The chemical composition of the electrode is the same as that used by Alvarez and his coworkers, i.e., saturated lead chloride, lead-mercury amalgam (3 per cent to 97 per cent) and copper wire connection. We, however, have omitted the stiff copper amalgam. The small inner tube is bent

\*From the Department of Psychology, New York State Psychiatric Institute and Hospital.

as shown, and a bulb  $\frac{1}{2}$  inch in diameter blown in the middle of the shorter arm, in order to give a larger cross-section to the amalgam lead-chloride junction. This design prevents spilling of the mercury in case the electrode is tipped. A graduation, etched on the equator of this bulb, serves to standardize the level of the mercury-lead amalgam.

This inner tube is mounted by thrusting it through one of the holes of a two-hole rubber stopper. A short tube (B), placed in the second hole, provides for the filling of the electrode and also serves as an anchor for the copper wire leading off from the electrode (C). This wire is run directly into the mercury-lead amalgam, thus eliminating the stiff copper amalgam used by Alvarez and his coworkers. The copper amalgam is inconvenient in assembly, tends to jar loose with use, and is unnecessary to the proper operation of the electrode. A semi-permeable membrane ("fish-skin" condom, washed in alcohol and ether)

Fig. 1.—Improved electrode. A, rubber stopper; B, open glass tube; C, copper lead-off wire loop for hanging electrode; D, sealing wax plug; E, level of lead chloride solution; F, etched graduation on inner glass tube; G, lead mercury amalgam in inner tube; H, semi-permeable membrane attached by rubber bands over end of 1-inch tube. The lip of the 1-inch tube allows the electrode to be held loosely in clamp, if desired.

stretched somewhat loosely over the bottom lip of the one-inch tube, furnishes a fairly constant moist conductor, and the slight bulge of the membrane under the weight of the solution in the outer tube gives a means of standardizing the pressure of the electrode on the patient's skin. Our experience indicates that electrode pressure on the skin may affect the potentials which are being measured.

A loop in the lead-off wire (C) furnishes a convenient means of hanging a fairly large number of electrodes inside a moist chamber to prevent drying of the membrane and evaporation from the electrode between daily experimental periods.

In actual practice, a single thickness of chamois saturated with lead chloride solution was placed between the electrode and the skin of the patient. It was found convenient to clamp the electrode loosely in a vertical position (with

| Four days later                          | March 10                               | 0.20             | 0.15 | 0.20 | 0.00 | 0.05 | 0.10 | 0.40 | 0.10 | 0.20 | 0.15 | 0.155                       | 0.0041                           |

patient prone), thus utilizing the weight of electrode rim and of the liquid on the membrane (*II*) as a standard pressure against the skin. The variation of potential differences on three different occasions between each of 10 different electrodes and a single reference electrode is shown in Table I.

The figures in the table represent 3 out of 20 such determinations, which were picked to illustrate the range of potential variation observed. The electrodes were in use on each day for from forty minutes to one hour. The first row of figures shows the variation of potential in millivolts for each of 10 electrodes on a given day and represents the greatest change observed. On this day the electrodes had been in use for a week or more. The second row represents change of potential during a similar period on the next day when the electrodes had been freshly assembled and, therefore, represents the operation of the electrodes under the most favorable conditions. The last row represents the variation of potentials after the same electrodes had been assembled for four days.

The next to the last column at the right of the table gives the average potential variation for the 10 electrodes in each case, and the final column, the average potential variation per minute. Both are in terms of millivolts. It is therefore evident that when the electrodes are freshly assembled, we may expect an average change of approximately 0.001 millivolts per minute, whereas after four or more days' use the electrodes are likely to develop a potential variation of 0.004 millivolts per minute or more. It is therefore recommended that for accurate work with body potentials, the electrodes be freshly assembled every four or five days or whenever a check of potential variation over a period of time shows sufficient change to affect the magnitude of measurements being made.

The figures of Table I were obtained when the electrodes were applied to the human body and under ordinary clinical working conditions, so that temperature of the electrodes undoubtedly varied due to transmission of heat from the body. The variation obtained is therefore not surprisingly large.

#### SUMMARY

A modification of the Alvarez, Freedlander, and Clark electrodes for use in measuring the potentials of the human body has been developed, as shown in Fig. 1. It possesses advantages over the previous electrode of the same general type: handy size, allowing the use of a large number of electrodes; practically the same nonpolarizing qualities as the Alvarez electrode; uniform pressure on the skin; ease of hanging in solution between periods of use; and comparative ease of assembly, which favors the use of electrodes which are in good condition.

In general we feel that our electrode is much more convenient for clinical use, and especially when used for measurements on psychopathic patients.

For the work of assembling and testing out the electrodes we are indebted to Mr. Joseph Barmack.

## A SIMPLIFIED PSYCHODOMETER\*

---

R. H. CHENEY, Sc.D., BROOKLYN, N. Y.

---

THE measurement of reaction time in fractions of a second following drug action in man has offered difficulties to investigators generally. The stop watch is costly and fragile in the hands of students. The split second timer described by Guthrie<sup>1</sup> in 1932, is not readily applicable to visual-mental-muscular reaction time tests. Dr. Metfessel's psychodometer is an excellent reaction timer for such psychophysiologic tests, but it is both complicated and expensive.

To obtain a less expensive, more rugged, and equally satisfactory apparatus for many types of experiments, the accompanying simplified modification of Dr. Metfessel's psychodometer was devised in connection with a study of the effect of caffeine upon the rapidity of mental and physical coordination and reaction in man.

The relatively simple psychodometer is illustrated in Fig. 1. It involves primarily the use of an impulse counter which records time intervals in one-hundred-twentieths ( $\frac{1}{200}$ ) of a second. The other parts can be assembled usually from miscellaneous equipment around any physical or physiological laboratory with very little expenditure.

The impulses were furnished by stepping down the 60-cycle alternating current of 110 volts to about 6 volts. Fig. 1 shows the apparatus to be quite readily portable and durable. Both of these factors are highly desirable in laboratory use. In Fig. 2, the schematic diagram of the psychodometer, check lights have been omitted in order to simplify the circuit. It was found that an assistant to the experimenter can easily check the accuracy of the subject's responses in performing the proper act in accordance with the stimulus given. For example, the tapping of the key corresponding to the color of the light stimulus flashed was required in most of the experiments. Auditory or other stimuli could be substituted for light.

The operation of the apparatus is very easy. It requires many more words and much more space to write or tell it than to do it. As the wiring shows in Fig. 2, the closing of a signal switch, for example, "S<sub>2</sub>," determines which of the

---

\*From the Physiological Laboratory of Long Island University.  
Received for publication, November 22, 1933.

possible lights will be flashed when the circuit is closed subsequently by the operator when he throws the double-pole, single-throw switch, " $S_1$ ." This latter switch also starts the impulse counter instantaneously with the flash of the light (red in this instance). Upon receiving the visual stimulus, the subject closes the proper key ( $K_2$ , in this instance) which stops the impulse counter, but does not put out the light until the operator opens the double-pole switch, " $S_1$ ." *Note:* As a matter of fact, in this simplified apparatus without the check light circuit, the tapping of any one of the keys  $K_1$ ,  $K_2$ , or  $K_3$ , stops the counter. The subject, however, is not aware of this fact and the operator's

Fig. 1.—Simplified psychodometer for human experimentation.

assistant observes whether or not the subject utilizes the correct key in accordance with the light flashed.

The operator is obscured behind his apparatus board (any large piece of wall-board serves effectively) in order that the subject cannot observe any of the operator's movements. The subject is seated at the opposite end of a 12-foot laboratory table with the subject's tap keys available. Wires of variable length may be used here to allow any desirable distance to intervene between subject and operator. The tap-keys are provided with large wooden discs so that the finger will not readily slip off, as the subject is required to hold the key down temporarily until the operator puts out the light by opening switch, " $S_1$ ." The operator's recording assistant is seated at a table near the subject

and in full view of the tap-keys. He notes any errors in the tap-key choice which the subject may make. The subject sits with his right hand on the table in front of the tap-keys and with his left hand resting upon his left knee. In this way, all of his movements to the tap-keys are as nearly equidistant as possible.

### MANIPULATION

The operator reads the stationary reading of the impulse counter and gives the dial number aloud, which is recorded by his assistant as the original reading for that trial. At variable time intervals after giving an original reading in each case, a light is flashed and the counter starts simultaneously. The subject observes the light flash stimulus, determines its color, and stops the counter by

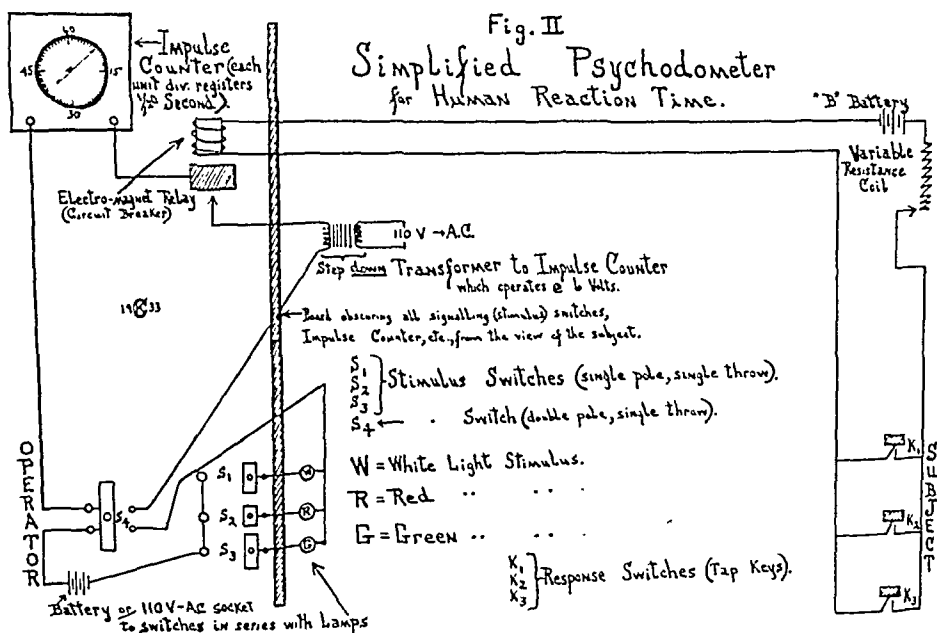

Fig. 2.—Schematic representation of simplified psychodometer for studies in human reaction times.

closing the proper tap-key. The operator then reads the dial number as the final reading for that trial. The difference between the two readings is obviously the total reaction time for this eye-hand mental decision, and muscular response-action phenomenon. Twenty-five trials or more may be averaged for greater accuracy.

The comparisons of reaction time under the influence of various drugs are compared readily, and their effect upon complicated psychophysiologic reaction times recorded quantitatively.

The valuable assistance of Professor Clarence J. Pietsenpol of the Physics Department and his assistant, Mr. Ralph L. Hirschel, is gratefully acknowledged.

## A MODIFICATION OF HILL'S RADIOPAQUE MASS FOR THE INJECTION OF LUMINA<sup>2</sup>

EDGAR J. POTH, PH.D., M.D.,† SAN FRANCISCO, CALIF.

A RELIABLE technic for the injection of radiopaque materials into the lumina finds many applications in anatomical, pathologic, and surgical studies of lymphatic, vascular, and duct systems. Probably the most satisfactory material for the injection of dead subjects is the bismuth oxychloride mass of Hill<sup>1</sup> when the suspension is properly made. Many workers, however, are unable to obtain consistently good results using the Hill preparation be-

Fig. 1.—An improvised jar or ball mill showing two fruit jars mounted in place and containing marbles. Speed, 10 r.p.m. A jar with a top adapted for injection is shown.

cause they cannot or will not follow the rather troublesome method of preparing the mass. A simple, easily duplicated method for the preparation of a uniform product has been evolved and will be described.

### PREPARATION OF THE SUSPENSION

The proportion of acacia to bismuth oxychloride taken is as one is to two. The quantity of water varies with the density of suspension desired. The unmixed ingredients are placed in a glass fruit jar or ball mill crock one-third filled with ordinary glass marbles. This is placed on a ball mill (Fig. 1), such as is commonly used by chemists for grinding materials extremely fine, and is allowed to grind for two to three days. These suspensions are still unstable and will settle out appreciably after standing several days, and

\*From the Department of Surgery, Stanford University School of Medicine.  
Received for publication, November 29, 1933.

†Fellow in Medicine of the National Research Council.

so it is advisable to regrind for an hour or two before making injections. Table I illustrates certain suspensions and designates their use.

TABLE I

| 165           | 330          | 500           | 650                   | 33.2                | 0.51                  | Arteries                      |

## INJECTION TECHNIC

a. *Lymphatics*.—Lymphatic injections are usually made with a Luer syringe fitted with a 27 gauge needle.

Fig. 2.—Injection system. A, Pressure regulator containing mercury topped with water to eliminate mercury spray. The inner tube can be raised or lowered so as to give the desired injection pressure. B, Mercury manometer. C, Fruit jar used in the grinding on ball mill shown with a top adapted for injection. D, Pressure regulating overflow trap containing mercury. The inner tube is adjustable to give the desired pressure in the venous tree. To be used only when visualization of the venous bed is required.

b. *Arteries*.—Arterial injections are best made by cannulating the artery and injecting under constant pressure using the system illustrated in Fig. 2, A, B, and C. The injection pressure is important and will vary with the density of the suspension, the end-result desired, and the species of animal injected. The small arterioles and capillaries are easily ruptured when a low density mass is injected under high pressure. The proper pressure for injection is readily determined and is best done by beginning the injection at a low pressure and then increasing the pressure in steps of 10 mm. of mercury, taking roentgenograms at each level of pressure. The injection is usually complete within five minutes. The interval of pressure throughout which satisfactory pictures are obtainable is sufficient that once it is determined for a species, it will hold for all individuals of this species (Figs. 3 and 4). Likewise, this is a good procedure to follow when injecting a valuable specimen.

c. *Veins*.—Simultaneous injection of arteries and veins produce confusing results because of the inability to differentiate between the arterial and venous systems. However, if the initial injection is made with a low density mass at a low pressure, a satisfactory outline of the arteries is obtained. Then, by increasing the pressure of injection and retarding the escape of the excess mass from the venous side by causing it to flow through a pressure regulating trap, Fig. 2, *D*, a roentgenogram of both arterial and venous beds may be

Fig. 3.—A photographic reproduction of a blocked-out roentgenogram of a rabbit injected at 120 mm. Hg pressure with a mass containing 0.5 gm. of BiOCl per c.c. No retouching has been done. Same animal as is shown in Fig. 4. The smaller vessels are lost in the reduction.

secured. Finally, a suspension of starch in acacia solution is substituted for the bismuth oxychloride mass, and the opaque material in the arterial tree is displaced. Since the starch suspension will not pass through the capillaries, a high pressure, 150 mm. Hg. is used in this injection. This will force the opaque mass out of the arteries and permit visualization of the venous bed without the interference of arterial shadows. All roentgenograms should be made while the injection pressure is maintained.

The best results are obtained when the injections are made immediately after death and before the blood has coagulated. If the blood has coagulated, the injection can be done after the clot has retracted and the serum separated.

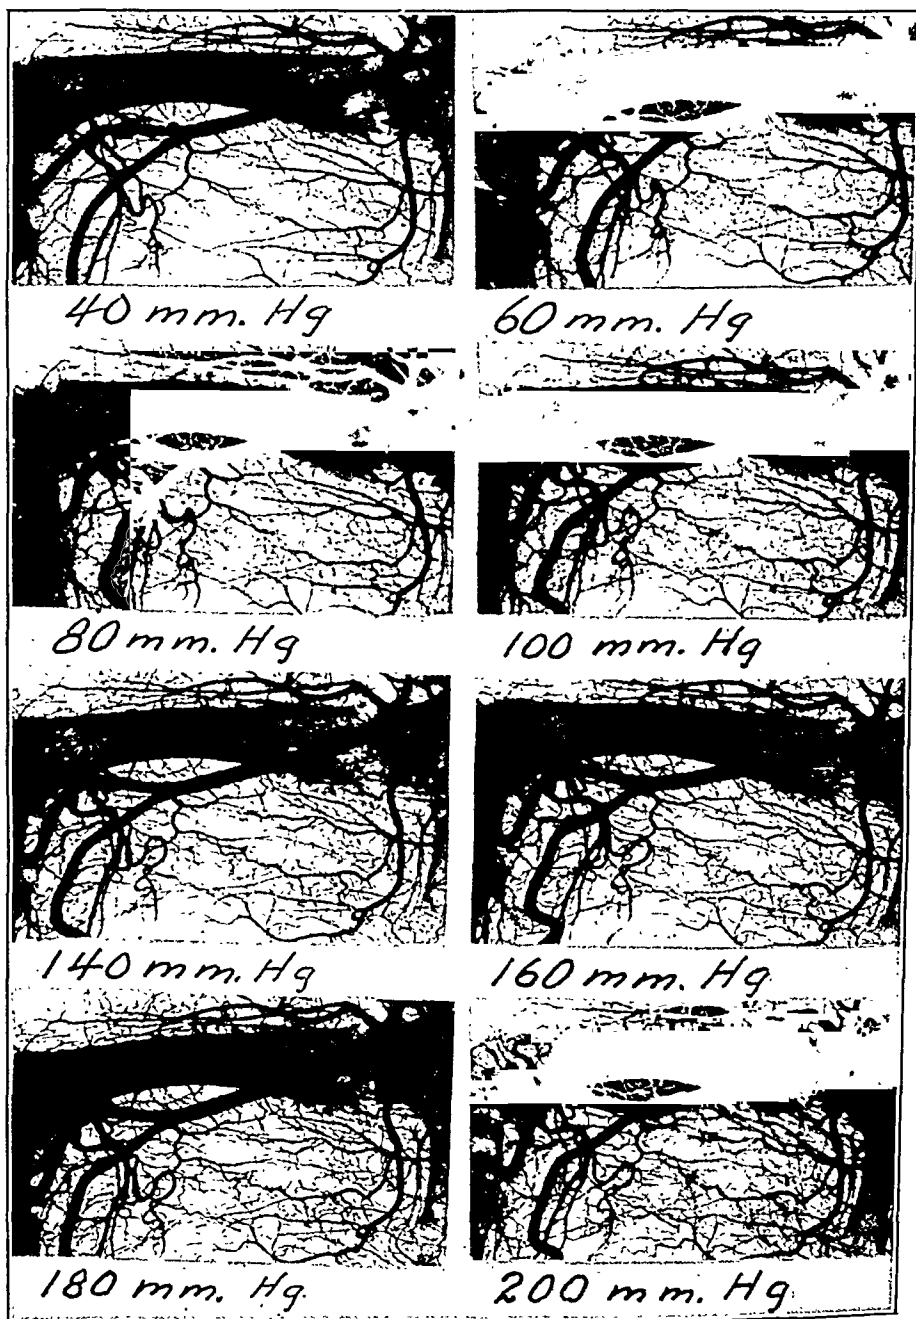

Fig. 4.—Right thigh of animal shown in Fig. 3. Injection pressure as indicated under each successive cut. These are contact prints from roentgenograms which have not been retouched. No vessels show rupture until a pressure of 200 mm. Hg is used; BiOCl extravasated into femur. Stereoscopic roentgenograms clearly show that the nutrient vessels of bones are visualized when injected at a pressure equal to the normal blood pressure of the animal.

With a little experience the proper density of suspension and the correct pressure for injection are readily selected for the problem at hand.

# DISCUSSION

Bismuth oxychloride makes a very satisfactory substance for injection, not only because of the high atomic number of bismuth and its consequent opacity to x-radiation, but, also, because of the physical properties of the compound. The bismuth oxychloride<sup>\*</sup> used in this work is extremely finely ground and will assume very definite physical properties when suspended and ground in acacia solutions. After grinding such a suspension for some hours in a jar mill the particles arrange themselves in chains less than  $\frac{1}{2}$  micron thick and from 3 to 4 microns long. Upon standing for fifteen minutes the chains arrange themselves into spherical rosettes about eight microns in diameter. No larger particles are formed regardless of the density of the suspension, except on long standing.

The greatest density of any mass suggested by Hill contains 0.4 gm. of BiOCl per c.c. and, as he states, this is a paste. By the method of preparation presented here, the most satisfactory mass for arterial injection contains 0.5 gm. per c.c. and has the consistency of a thin cream. Injection of this material at a pressure equal to the normal blood pressure of the animal usually gives satisfactory visualization of the arterial tree extending out to minute arterioles without the fogging attendant upon capillary shadows.

With a minimum expenditure of effort, exacting no individual skill, the mass described can be prepared, and it will have uniform and reproducible composition and physical properties.

# SUMMARY

1. A simple, easily duplicated method for the preparation of a uniform, radiopaque mass, which insures complete injection of lumina, is presented.
2. An injection technic is described.
3. Methods for obtaining visualization of both arterial and venous beds are outlined.

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

---

**THYMIC HYPERPLASIA:** Follow-Up Study of 30 Cases, Wadlbott, G. L., and Anthony, G. E. *Am. J. Dis. Child.* 47: 34, 1934.

Of a group of 102 cases in which the diagnosis of status thymicolymphaticus was made by various pathologists, 34 were selected in which no adequate cause of death had been determined. Sixty-eight cases were excluded since other conditions, such as hyperthyroidism, birth trauma, gastroenteritis, and respiratory infections, were associated with lymphoid hyperplasia, and in themselves were sufficient to cause death.

In 11 of the 34 cases death occurred without previous illness, and there were no pathologic lesions to indicate the presence of a previous illness. In 16, minor, usually nonfatal, incidents preceded death. In 7, a syndrome developed manifesting dyspnea, stridor, fever, and shock.

The lungs of all these patients presented uniform changes, characterized by capillary congestion, extravasation of blood cells, and edematous fluid. These lesions alternated with areas of emphysema and atelectasis. In 17 cases petechial hemorrhages were present, involving the heart, pleura, lymph glands, and various other viscera. In some, there were dilatation of the right side of the heart, degenerative changes in the liver, and edema and capillary congestion in other organs than the lungs. Hypoplasia of the suprarenal glands and hyperplasia of the lymphoid organs, as noted by other authors, were present.

Comparison of this pathologic process with that reported in anaphylactic shock in man reveals a close resemblance, if not a complete identity, of the two conditions. Eosinophilia of the tissues and an allergic family or personal history point further to this conception.

On the basis of these findings, it is believed that death may be the result of a primary anaphylactic edema of the lungs and ensuing asphyxiation. Such a theory can be upheld only if one assumes: (1) that anaphylactic shock may occur from incorporation into the body of nonprotein substances; and (2) that absorption of shock-producing antigen may take place by ways other than by injections. Evidence is presented, both from personal experience and that of others, which tends to confirm these facts.

**BLOOD LIPIDS, in Children With Scarlet Fever and Rheumatic Disease,** Kaiser, A. D., and Gray, M. S. *Am. J. Dis. Child.* 47: 9, 1934.

Values for blood lipids in 29 normal children between the ages of five and sixteen were fairly constant, but were considerably below the accepted averages for normal adults.

Values for blood lipids in 43 children convalescing from scarlet fever were practically the same as in normal children. Deviations from the mean were considerably greater, especially for cholesterol.

Similar values for lipids were found in 22 children with acute rheumatism and in 20 with chronic rheumatism. The standard deviations were much greater for the children with rheumatism than for the normal children.

Values for blood lipids deviated considerably from the normal in nephrosis and in nephritis.

Values for blood lipids were not influenced by ordinary variations in diet. The deviations from the mean noted in normal and in sick children seemed to bear no relationship to an increased or diminished intake of fat and of carbohydrates.

No appreciable difference was noted between determinations made on boys and those made on girls. Similar deviations were found in both sexes.

Determinations made in the summer months were uniformly lower than determinations in the winter months.

Studies on the blood lipids of children with rheumatic disease and with scarlet fever revealed values similar to those found in normal children. The standard deviation from the mean was considerably greater in the children with these infections than in the normal children. It is quite likely that the infection, rather than the varied amount of fat ingested, was responsible for the increased deviations.

**SEMEN: A Differential Stain that Advances the Study of Cell Morphology, Cary, W. H., and Hotchkiss, R. S. J. A. M. A. 102: 587, 1934.**

The gross examination includes a notation of the amount, which, when complete, and from men under forty years of age, should exceed 3.5 c.c. Lesser amounts should arouse suspicion of deficiency and premature weakening by vaginal acidity, otherwise negligible. Extended periods of sexual abstinence may impart a slightly yellow tinge to the normal grayish opaqueness. Normal specimens commonly show a slight degree of viscosity, which is easily demonstrated by slowly expelling a drop of semen from a pipet. Absence of viscosity with a lessening of opaqueness points to reduced cell content, although the reverse deduction does not hold.

An alkalinity giving a pH of from 8.1 to 8.4 has been so constant that it seems an unnecessary refinement except in research study.

Two specimens, one thick and one thin, are promptly prepared for microscopic examination. This is done by gently protecting a full drop and a fractional drop with cover glasses, the former permitting a gross impression of the density and motility of the cellular content, the latter allowing a preliminary study of individual cell morphology. In the thicker preparation, semen of relatively high fertility presents a field teeming with spermatozoa, many of which are rapidly propelled by fast-whipping tails. While universal cell activity would constitute the ideal, one usually notes in comparatively vigorous specimens that these fast travelers are colliding with a certain number of inactive (25 per cent average) and a variable number of sluggish and impotent cells, which gradually sink toward the lower strata of the field. Familiarity with this picture under standard, dry, high power magnification constitutes the measure by which motility is judged. It is a practical observation that a motile field, though definitely subnormal, is apt to convey a favorable impression on the inexperienced or occasional examiner, but reverse errors in interpretation are rarely made. In the author's experience the practical aspects of motility are that a large number of highly motile cells are essential to fertility; and when a specimen of normal quantity and rich cellular content shows 25 per cent or more of these dynamic cells, a rating of relative fertility must be assumed unless strongly disproved by other indexes to be described. Such specimens usually meet other major requirements of fecundity.

The following technic permits illustration of the head, midsection, and tail of the sperm.

A. Prepare thin cover slip smears as used in the preparation of blood for staining.

B. Fixation in Schaudinn's solution:

1. Immerse for one minute in 7 per cent solution of corrosive mercuric chloride, 2 parts, and absolute alcohol, 1 part.
2. Immerse for one-half minute in 50 per cent alcohol.
3. Immerse for one-half minute in distilled water, 3 ounces, and tincture of iodine, 2 drops.
4. Wash in tap water.

C. Staining Process:

1. Immerse for one-half minute in aqueous solution of eosin, 5 per cent.
2. Immerse for one minute in 50 per cent alcohol, 3 ounces, and concentrated hydrochloric acid, 2 drops.

3. Wash in distilled water.
  4. Immerse for two and one-half minutes in hematoxylin.
  5. Immerse for one minute in distilled water, 3 ounces, and glacial acetic acid, 2 drops.
  6. Wash in distilled water.
- Dry and mount.

In appraising seminal specimens, deduct the percentage of abnormal forms found from the total cell count. The resultant figure, when correlated with other data, is of great importance in the more accurate evaluation of the semen. For instance, 40 per cent of inactive cells with 25 per cent abnormal forms would indicate more serious impairment and need for greater improvement in a specimen with a count of 60,000,000 or less than would obtain with a cell count of 100,000,000.

**ENTERITIS: Acute, in Infants and Young Children: Bacteriologic Studies, Cooper, M. L., Keller, H. M., and Johnson, B. Am. J. Dis. Child. 47: 388, 1934.**

The bacteriologic methods presented were used in the isolation of streptococci from 65 per cent of 46 infants and children with acute enteritis.

Morphologic and cultural characteristics of these streptococci alone were found to be insufficient for identification.

Marked similarities in the fermentations of carbohydrate were noted in the streptococci isolated from the involved intestinal tracts of patients at necropsy, from the stools of patients, from the throats of patients, and from the intestinal tracts of animals which had received injections.

All the cultures were insoluble in bile with the exception of two, which were questionably so.

For the reasons stated it is suggested that the term *Streptococcus micro-apoikia* (small colony) be employed to designate this group of microorganisms, and that the term *Streptococcus micro-apoikia enteritidis* be employed to designate the strain responsible for the production of enteritis in the patients who were the subjects of this study.

**BLOOD, Studies of in Normal Pregnancy, Dieckmann, W. J., and Wegner, C. R. Arch. Int. Med. 53: 188, 1934.**

Previously reported hemoglobin, hematocrit, and erythrocyte values in pregnancy are, in many instances, at variance with each other, and the results are inconclusive because, with but few exceptions, the determinations were made with methods and apparatus which were not standardized, and they were not made on the same women throughout pregnancy. They are of value only in that they indicate the direction of the change.

Determinations of these constituents and of the blood volume were made on various groups of women for the different periods of pregnancy. While the means show a decrease in each substance, reaching a minimum in the last ten weeks, calculation of the difference between the means demonstrates that the change is of no significance.

Similar studies in which the same women were followed throughout pregnancy and the puerperium indicate that the following changes occur in the blood:

There is a definite decrease in the hemoglobin per hundred cubic centimeters of blood. The maximum decrease, amounting to 15 per cent, is from the twenty-sixth to the thirty-fifth week. At two weeks postpartum the hemoglobin is 17 per cent, and at eight weeks it is 14 per cent, below normal.

There is a slight but definite decrease in the hemoglobin per kilogram during pregnancy, and a more marked one after delivery. Apparently there is an attempt during pregnancy to compensate for the increase in tissue by increasing the hemoglobin, but postpartum the stimulus is gone, and there is a lag in the production of hemoglobin.

The changes in the hematocrit value are similar to those in the hemoglobin content. The maximum decrease during pregnancy is 11 per cent. The recovery after delivery is more rapid, although at eight weeks postpartum the hematocrit value is still below normal.

The changes in the erythrocytes are also similar, but the count is normal at three weeks postpartum, thus demonstrating the ability of the hematopoietic tissue to produce red cells but its inability to stock them with the normal amount of hemoglobin.

The total amount of hemoglobin shows an average increase of 13 per cent, but individual cases show a marked gain during pregnancy and a retention of much of the gain postpartum.

The total cell volume shows an average increase of 20 per cent, which is even greater in many individual cases, and a retention of many of the cells postpartum.

The increase in plasma volume is definitely greater than the increases in cell volume and hemoglobin. Therefore, these constituents show a relative decrease and an absolute increase.

Since the erythrocyte is only a vehicle for transporting hemoglobin and since cell counts in pregnancy are often misleading, more time and care should be devoted to hemoglobin determinations.

In pregnancy a hemoglobin content under 10 gm. per hundred cubic centimeters of blood should be diagnostic of anemia.

The changes of blood volume, cell volume, and hemoglobin are a part of the mechanism by which the body is able to take care of its own increase in tissue and the metabolism of the fetus, with the expenditure of the least amount of work.

**ANEMIA, Etiology and Treatment of in Pregnancy, Strauss, M. B. J. A. M. A. 102: 281, 1934.**

The "physiologic anemia" of pregnancy is only the effect of hydremia.

The hypochromic anemia of pregnancy is due either to a direct dietary deficiency or to a deficiency conditioned by gastric anaecidity, hypoaecidity or associated defects in the presence of the fetal demand for blood-building materials. It may be completely relieved, either during or after pregnancy, by the administration of iron in suitable (usually large) doses.

The macrocytic anemia of pregnancy is generally due to a temporary lack in the gastric juice of a specific intrinsic factor, which has been shown to be absent from the gastric juice of patients with Addisonian pernicious anemia in relapse. The ultimate complete return of this factor after delivery is hypothecated. In other cases the lack of the extrinsic factor (associated with vitamin B) from the diet may produce similar effects. The macrocytic anemia of pregnancy ordinarily may be completely relieved with liver extract although iron is frequently required in addition.

There is some similarity of the etiologic mechanism involved in the hypochromic anemia of pregnancy and idiopathic hypochromic anemia in the absence of pregnancy, and in the macrocytic anemia of pregnancy and Addisonian pernicious anemia.

The development of anemia in pregnancy may best be prevented by supplying the pregnant woman with an adequate intake of blood-building materials.

**SYPHILIS, Transference of Inguinal Glands in Human, Lunsford, C. J. and Day, P. W. J. A. M. A. 102: 448, 1934.**

The results obtained from the intratesticular inoculation of rabbits with human material from 100 cases of syphilis with a 4-plus Wassermann reaction were as follows:

In 8 cases of primary syphilis 100 per cent of the gland transplants caused positive results in live rabbits.

The glands of 24 patients with chronic syphilis who were under treatment caused negative results in rabbits.

In 38 per cent of 29 cases of untreated latent syphilis, the results in rabbits were positive.

For 6 patients with untreated dementia paralytica inoculations into rabbits gave negative results.

The glands of 12 of 38 patients previously treated for chronic syphilis gave positive results. Six of the 12 patients had received intensive treatment, averaging fifty-two injections of neocarsphenamine and forty-six of mercury.

Three patients with acute syphilis who were adequately treated according to present standards showed live *Spirocheta pallida* in their inguinal glands after a lapse from treatment extending from three to five years. The conditions were diagnosed early; the patients were treated intensively and later were pronounced cured on the evidence of completely negative clinical and serologic findings.

It is concluded that:

1. The diagnosis of primary syphilis by means of gland puncture can be made in 100 per cent of cases.
2. It is probable that patients with late syphilis are not a menace to others while undergoing active treatment.
3. A comparison of the 31.5 per cent positive results obtained in previously treated patients with syphilis with the 38 per cent positive results obtained in untreated patients indicates that, from the standpoint of the biologic cure of the patient, inadequate treatment is very little better than none at all.
4. According to our findings, *Spirocheta pallida* is not present in the cerebrospinal fluid.
5. There is a necessity for frequent reexamination of patients with syphilis, even though it appears that they have been adequately treated according to modern standards.
6. The clinical and serologic tests used as criteria of cure in syphilis are inaccurate and must be revised with increasing knowledge of the disease.

**TISSUE, Traumatic Epithelial Cysts of the Skin, Wien, M. S., and Caro, M. R. J. A. M. A. 102: 197, 1934.**

Traumatic epithelial cysts develop as a result of injury to the skin, usually produced by a blunt or tearing instrument. Such cysts occur most often on exposed sites, such as the fingers and palms, and are especially prevalent in those occupations which predispose to injury.

The origin of the cyst is most probably from a bit of epidermis which has been torn from the surface and implanted in the corium. It may also originate from deeper epithelial structures in the absence of surface injury. Here the cyst may form about a foreign body by proliferation of epithelium from the hair follicles or the glandular structures of the skin. Occasionally a foreign body granuloma with cyst formation may simulate an epithelial cyst of traumatic origin.

**LEUKEMIA, Monocytic, Leukemic Reticulo-endotheliosis, Foord, A. G., Parsons, L., and Butt, E. M. J. A. M. A. 101: 1859, 1934.**

Leucemic reticuloendotheliosis (monocytic leucemia) is a distinct condition characterized by the presence of a clinical picture similar to that in other acute leucemic states and the presence of an extraordinary number of monocytes in the blood, usually immature forms. Pathologically, a diffuse enlargement of the lymph nodes, spleen, and liver is found, and in the microscopic examination of the tissues, widespread proliferation of reticuloendothelial cells is found, to a degree as great as or greater than is usually found in the so-called infiltrates of other leucemias.

A report of four cases conforming to the foregoing feature, with autopsies in two and biopsy in one, is given.

### Have Hospitals Attained a Standard of Mediocrity?

NOT so very many years ago there were numerous hospitals, many of them relatively large institutions, in which the standards of medical practice and the type of care given to patients were notoriously far below what should be and ought to be expected and demanded.

Realizing this situation—and, occasionally, it was very bad, indeed—the American Medical Association and the American College of Surgeons inaugurated a program of hospital standardization whereby a minimum standard of efficiency was formulated to which all hospitals must conform to be “approved.” The teeth in this edict lay in the fact that no unapproved hospital was deemed suitable for the training of resident physicians without whom few hospitals can function.

As a result, there are today very few hospitals which have not made such changes as were necessary to secure approval, which does not, however,

signify that all "approved" hospitals have now reached and maintain a high standard of efficiency.

If there be, as probably there are, those who doubt this statement, their attention may well be directed to the remarks of Dr. H. A. Christian, Professor of Therapy and Practice of Medicine in Harvard University Medical School.

In the course of an address delivered before the Congress of Medical Education, Medical Licensure, and Hospitals in 1931<sup>4</sup> he said:

"Present efforts at hospital standardization have attained a fairly satisfactory level of mediocrity for hospitals. A few, often perfunctory, changes in past practices of a hospital now will secure for it a Class A rating. The very poor hospital has been forced to improve, and this is the only real good that has resulted from all the work of those organizations which have been concerned in the classification and rating of hospitals.

"Many institutions, instead of receiving vigorous stimulation for betterment, are basking in the calm complacency of Class-A-dom. Regulations of the classificationists are cheerfully omitted in the case of the best hospitals in the realization, perhaps the subconscious realization, of the mediocrity of their standards and the probable deterioration that would result in these hospitals from their uniform enforcement.

"If there is to be any official standardization of hospitals new standards should be set. At present far too many hospitals are rated as satisfactory, that is, are Class A hospitals, for such rating to have much value or to be any real stimulus to improvement. We are too much in the condition of a heaven peopled by perfect beings, the angels. Fewer hospitals should be Class A than at present is the case; in other words, there should be fewer angels."

That these comments are not without some basis the impartial observer will not dispute.

It may be true that monthly staff meetings are held, as required, but how often are they inspiring and how often do the reports of services lead to critical debate or constructive criticism? How often, on the contrary, do they degenerate into mutual admiration societies?

Constructive criticism, debate which leads to study or to fruitful thought should never be painful nor reluctantly received for, as Herbert Spencer wrote:

"Mankind in its progress passes through three stages: the unanimity of the ignorant; the disagreement of the inquiring; and the unanimity of the wise."

Hospital records alone, now proudly displayed by all "approved" hospitals, furnish many startling and at times amusing illustrations of perfunctory emphasis upon ridiculous detail and equally perfunctory compliance with the requirements of hospital standardization.

The purpose of the hospital record is obvious and elementary: to supply for future contingencies a clear, succinct recital of events from which a clear reconstruction of the situation can be formed in the mind of the reader. A story so plain, so complete, yet without verbosity, that any one can readily understand why such a diagnosis was formulated, and just why a particular

method of treatment was followed, or a specific operation was necessary. The record need not be voluminous but it should be thorough, clearly phrased, and complete in its data of a particular case.

Let those who have attempted to utilize hospital records in the compilation of statistical data or the preparation of papers testify if the majority of records in the majority of hospitals conform to the requirements listed.

The following editorial from an official bulletin of the Philadelphia County Medical Society offers these comments:

"Hospital records are voluminous and cover everything that can be discovered concerning the patient, but in many instances are shy such minor details as to which arm or leg or eye was operated upon, why the operation was done, how the operation was done, and an exact statement of the degree of restoration to normal on discharge. These details, when omitted, are filled in from the fertile imagination of the medical attendant at large. It is seldom, indeed, that any hospital record cites the indication for a first operation and much rarer that it mentions the indication for a second operation. On the other hand, the emotional variations of the midnight hours are engrossed for posterity with infinite care by the night nurse in charge, and the marital affairs of the blood cells and bacteria set down with mathematical accuracy bearing unanswerable testimony to the fact that the technician, reached at least the eighth grade."

That examples may be found, and readily, to justify these strictures will require no extensive investigation. Few, indeed, are the "histories" which could be used verbatim in a scientific report.

It may well be suggested, with all due respect to the "approving" organizations, that in the inspection of records, it might be advantageous, not merely to tick off the fact that records are made and filed but to ascertain exactly *what kind* of records.

It is quite true that standardized records are practically a *sine qua non* in standardized hospitals, that they are inevitably or generally, therefore, good records is, to speak mildly, open to grave doubt.

Record inspection will invariably present an orderly array of neatly bound sheets which, through their number, their variety, and the stereotyped marginal printed guides, tacitly make claim to the desirable and admirable quality of thoroughness.

And yet one of those responsible for their existence in later years has this to say of them:

"In a medical ward of a class A teaching hospital I recently saw a Jewess, aged forty-five years. Five minutes' conversation brought out the facts that she had always been in reasonably good health until after the death of her husband a year ago; that she then looked hopefully for support from her eldest son; but that about three months ago she gradually experienced the final and crushing conviction that his talents were limited to the selling of newspapers, which yielded a profit of less than a dollar a day. She therefore, in addition to caring for her home and the younger children, took employment in a restaurant, standing eight hours a day washing dishes. Then came backache, sleepless nights of worry, anorexia, loss of 20 pounds, nervousness, utter

exhaustion, and hospitalization. Cursory examination revealed only the ordinary effects of such a life, including possibly some thyroid disturbance.

"Now, I ask of you sticklers for form and order, what do you suppose that woman's folder contained? Five and one-half closely written pages of matter comprised under twenty-eight captions, all neatly underlined with red ink and ruler! Figure out the time that probably took, and then ask yourselves how much time and energy remained to devote to the clinical problem of that woman. We toil through those five and one-half pages in search of useful bits of information. Here and there we find a few, fragmentary and uncorrelated. In the place for 'social condition' is stated that she is a widow; under 'occupation' it is stated that she is a 'housewife'; under 'marital history' that she has four children, but not a word about that fiasco of the eldest son. The paragraph on 'habits' speaks of loss of weight but gives no hint of the possible cause. Breathlessly we work down to the captions 'complaint,' 'onset of present illness,' and 'course of present illness' and find only some sketchy references to pains in the back, palpitation, breathlessness on effort, gas in the stomach, and so on, but never a word of the restaurant or the thoughts in the poor woman's head. Then comes the sacred array of paragraphs on the various systems, with reiteration of shortness of breath under 'cardiorespiratory system,' of stomach gas under 'gastro-intestinal,' etc., etc.

"The writer of this history was evidently painstaking and industrious, and yet what a mess he made of it! There is not the slightest doubt that if, before he ever set foot in the medical school, he had been confronted with this patient and had been asked to write down what he could find out about her condition, he would have done incomparably better. And as a commentary on the teaching of clinical history taking is not that the height of irony? The reason for this enormity is obvious. The writer of the history has been so occupied in constructing and polishing the frame in order to meet the standard specifications that he has been unable to paint the picture; indeed, he has scarcely seen the patient and her experiences at all.

"This case, to be sure, is worse than many of our hospital clinical histories, but it is none the less a good illustration of a valid general criticism of unrestrained standardization; namely, stereotypism, perfunctoriness, mediocrity. And, parenthetically, the criticism is applicable beyond the subject of clinical records. I have heard members of a hospital staff oppose betterments in organization for the reason that the hospital was already accredited by the American College of Surgeons and the college did not require the change."

Criticism is most valuable when constructive and the suggestions of the same author are therefore worthy of interpolation:

"1. That we abandon the effort to amplify records for the purpose of future statistical researches except for specific objectives in institutions where there is a reasonable prospect of continuity and reliability of data to justify the effort.

"2. That teachers and those who presume to examine hospitals for accrediting purposes shift the emphasis from form to content, that they recognize

merit in any form in proportion as it aids in clarifying the individual case, and demerit in proportion as it exhibits aimless wandering, irrelevant matter, redundancy, disjointing of related facts, or otherwise clouds the issue.

"3. That the technic of history taking be regarded as an intellectual rather than a mechanical process. Histories should exhibit uniform clue-mindedness rather than a uniform system of headings and paragraphing. The record of important phenomena, such as weight loss, blood vomiting or edema, should show in the immediate context the effort to assemble the available historical evidence for or against the various possibilities suggested.

"It will be argued that such freedom in composition may be all right for mature clinicians but not for students; that the latter will overlook important data if they are not required to include all the conventional paragraphs. Of course they will; but so are they under the present burdensome regime; and it is better that they miss some of the kernels of grain while actually looking for them than that they miss them through being more occupied by an elaborate sorting of the chaff."

It is probable that more than one hospital pathologist has been impressed with the multitude of careful and varied preoperative studies carried out during the preparation of the fifty cases required for obtaining the coveted F.A.C.S. and likewise somewhat nonplussed to note their abrupt cessation after the initiation ceremonies are a matter of history.

What conclusion is a Resident Physician to form from such a happening: that such studies are valuable and necessary; that they were based upon real indications in fifty consecutive cases which indications were then no longer to be found; or that they are simply "the bunk"?

What value can he attribute to the histories the sole reason for writing which is that the patient is to be discharged, or the "progress notes" compiled when he has gone home?

It is undoubtedly true that Resident Physicians have been to a greater or lesser extent benefited by the compulsory reformation thrust upon hospitals. They have cause to be thankful that the days have passed when all the emphasis was laid upon the duty the interne owed to the hospital and precious little upon what the hospital owed to the interne.

But the millennium is not yet here and one wonders what would accrue if it became the custom for internes to report, when their hospital days were over, to their Dean who advised them in their student days as to internship, their honest opinion as to their experience, their summation as to what they learned and from how great a proportion of the staff, and to what exact degree, as testified to by actual experience, the "approved" hospital justifies its rating.

It is obvious that by far the greater number of those who embark upon the interne year receive their training, not in great medical centers, not in well-equipped and well-manned clinics, not in hospitals with teaching affiliations, but in the average hospital of moderate size. Nor is it always true that those under whom they serve, with whom they are associated in this formative period which often does and always should exert a profound and powerful influence upon the manner in which these young men will later

practice their profession, are necessarily possessed of the teaching instinct or the ability to pass on to others the lessons they themselves have learned in the School of Experience.

If, as a result of his experience, the Resident Physician does not emerge from his hospital year richer in knowledge and enthusiasm, inculcated with the idea of honest, earnest care and thoroughness in the study of his patients, inspired to give to the life work he has chosen the very best that is in him, and thoroughly imbued with the necessity for continual effort to improve his knowledge and ability; and if the lack of these ideals and qualities can be laid at the door of the hospital and its staff, then that hospital has but ill fulfilled its duty toward the interne, has but ill discharged the responsibility which it has assumed toward him, and ill deserved the "approved" status which it doubtless possesses.

And, by the same token, the Dean or the School by whose advice or with whose tacit assent the student seeks and accepts such an appointment, have ill deserved the confidence and belief he has given them.

"Approved" hospitals do not by mere virtue of that fact necessarily become good hospitals nor, and the two are by no means synonymous, efficient centers of postgraduate instruction.

One's travels need not be wide nor his experience with hospitals extensive to grant the truth of this statement.

It is impossible to reach perfection in a single stride; the standardization program, without doubt, was not regarded by its originators as achieving perfection. But there seems reason to wonder if its initial impetus may not have subsided into a gentle stroll along well-defined but narrow pathways; if the early desire for improvements in order to secure approval may not have simmered down to the gentle "complacency of Class-A-dom"; and if its main result is not in some danger of becoming simply a "standard of mediocrity."

## CLINICAL AND EXPERIMENTAL

### STUDIES IN BACTERIOPHAGE\*

#### I. THE BEHAVIOR OF THE BACTERIOPHAGE AND THE BACTERIA IN THE LESION AFTER THE TREATMENT OF ACUTE STAPHYLOCOCCUS SKIN INFECTIONS WITH BACTERIOPHAGE

HELEN ZAYTZEFF JERN, M.D., EDWARD L. HOWES, M.D., AND  
FRANK L. MELENEY, M.D., NEW YORK, N. Y.

#### INTRODUCTION

IN THIS and in several subsequent papers we shall endeavor to report our laboratory observations in connection with the clinical use of bacteriophage. In reviewing the voluminous literature on the subject of bacteriolysis since the first reports by Twort<sup>1</sup> and d'Herelle<sup>2</sup> one finds that most of the articles fall into two groups: one confines itself to various aspects of the phenomenon in the test tube, while the other concerns itself purely with its clinical application. Only a few authors have reported experiences with the bacteriophage both in the clinic and laboratory and have attempted to set up controlled conditions for their observations. The reports of test tube phenomena have been contributed largely by investigators trying to work out some of the fundamental principles of the reaction, without attempting to apply them clinically. Their work has been of prime importance for our understanding of the nature of the phenomenon and for establishing a rationale for its use, but many of the phenomena which have been observed in vitro cannot be duplicated in vivo, and most of the reports of the clinical application of bacteriophage indicate that the results obtained have been poorly controlled by laboratory observations. The majority of clinical reports have been favorable.

\*From the Bacteriological Research Laboratory of the Department of Surgery, College of Physicians and Surgeons, Columbia University, and the Presbyterian Hospital.  
Received for publication, November 20, 1933.

Failures have seldom been published. One does not persist in a method of treatment which does not have some degree of success. Therefore, only those who have had success have been able to collect a series of cases sufficiently large to be impressive, but it may be seriously questioned whether bacteriophage actually changed the course of some of the self-limited diseases which have been treated with it. The commercial exploitation of bacteriophage has resulted in its wide use by physicians who are not in a position to determine the potency of the products which they employ and who have made no attempt to set up control series sufficiently large to make it possible for them to properly evaluate their results.

We seriously question the wisdom of this uncontrolled use of bacteriophage at the present stage of our knowledge, because its successful use probably depends upon a combination of conditions intrinsic in the patient, in the bacterium concerned, and in the lytic principle available, as well as upon the manner in which these are brought together. Certain minimal essentials would seem to be required for success, a potent bacteriophage, a susceptible infecting organism, an adequate and intimate contact of bacteriophage with infecting organism, and an environment favorable to or at least not antagonistic to the interaction of these two. If the four conditions for success are absent or only partially fulfilled, bacteriolysis, *in vivo*, can hardly be expected to occur. It is not likely to occur with an impotent bacteriophage, with a resistant strain of bacteria, with poor contact of bacteriophage with organism or in an environment unfavorable or antagonistic to the interaction of these two. Whatever benefit may accrue from the injection or administration of the lytic products of bacteria as antigens has been given very little consideration. The whole procedure is still in the experimental stage and unless an effort is made to find out what the necessary conditions for success are and how to set them up, failure will be the rule and the whole subject will be brought generally into the disrepute in which it already finds itself, in the minds of some of the more conservative clinicians and bacteriologists. Extravagant claims for bacteriophage have been made largely by hyperenthusiasts or by those financially interested in its commercial success. This situation is to be deplored, for it seems fairly certain that in the hands of some critical investigators, favorable results have been obtained, results which at times have convinced both the physician and the patient that bacteriophage has some virtue as a method of therapy.

We have been impressed by incidents of this kind and have set out to clarify, if possible, certain obscurities with regard to the behavior of bacteriophage after its injection into the body and the behavior of the bacteria in the lesion after subjecting them to contact with the bacteriophage. In this paper we shall consider the following questions:

1. Does the hemolytic property of certain strains of *Staphylococcus aureus* bear any relationship to their resistance or to susceptibility to bacteriophage?
2. Do the bacteria in the lesion change their cultural characteristics after a single injection of bacteriophage?
3. Do the bacteria become more susceptible or more resistant to the action of bacteriophage?

4. Are the bacteria destroyed in the lesion by the action of bacteriophage?
5. Does the injected bacteriophage persist for any length of time in the lesion?
6. Does the injected bacteriophage increase in potency or amount in the lesion as d'Herelle has claimed?<sup>3</sup>
7. Does the bacteriophage injected at a site distant from the lesion reach the lesion through the circulation and multiply at the expense of the bacteria there?
8. Does the bacteriophage inhibiting substance (antiphage) found in the blood serum of some individuals inhibit the action of bacteriophage when injected into the lesion?
9. Can the apparently favorable effect of bacteriophage treatment in some cases be correlated with the absence of antiphage in the blood, the persistence of bacteriophage in the lesion or any other laboratory finding?

### LITERATURE

The only reports bearing upon these questions which we can find in the recent literature are the following: In the treatment of a small group of twelve cases of urinary infections, Caldwell<sup>4</sup> found that after subcutaneous injection of bacteriophage it could be isolated from the urine. When bacteria disappeared from the urine following bacteriophage therapy the bacteriophage could no longer be recovered from the urine. She noted that the growth and pigment characteristics of the bacteria changed strikingly under bacteriophage action. In those cases in which the urine was not rendered bacteria-free following the use of bacteriophage the bacteria were modified and became resistant. The bacteriophage-resistant bacteria grew in smaller colonies than the original culture.

In 1926, Schumm and Cooke<sup>5</sup> looked for spontaneous bacteriophage in the washings of 40 cases of maxillary sinusitis and found it in four. In 11 of the negative cases, all of which were chronic, 1 c.c. of bacteriophage was instilled at weekly intervals, but no favorable results were obtained, although bacteriophage could subsequently be recovered from a majority of these cases and the organisms cultivated from the lesions remained susceptible to the bacteriophage in the test tube.

In 1926, Epstein and Fygin,<sup>6</sup> employing horse-blood agar, reported that 31 strains of hemolytic staphylococci were resistant to bacteriophage, while 91 nonhemolytic strains were susceptible. McKinley and Camara<sup>7</sup> (1930), working with a bacteriophage which was active against a strain of nonhemolytic staphylococcus, failed in their attempt to adapt it to 7 hemolytic strains. They believed that this observation tended to confirm the work of Epstein and Fygin, and suggested that this might explain the relative virulence of hemolytic organisms. Contrary results, however, were recently obtained by d'Herelle and Rakietsen<sup>8</sup> who studied cultures from a hundred cases of staphylococcus infections, using human and rabbit blood agar. Seven strains of nonhemolytic staphylococci, isolated from chronic cases of furunculosis, sinusitis and osteomyelitis, were resistant to a number of polyvalent bacteriophages, while 71 strains of hemolytic staphylococci, with one exception, were found to be susceptible to the bacteriophage. The remaining 21 nonhemolytic strains were finally lysed, but in several instances only after repeated contact with the bacteriophage. These results were so at variance with the work of the preceding authors that d'Herelle and Rakietsen repeated their experiments with horse-blood agar and found that the hemolytic strains were just as susceptible on that medium as they were on human and rabbit blood agar.

In 1931, Applebaum and McNeal<sup>9</sup> reported that purulent exudates and blood as well as serum, inhibited lysis sufficiently to explain the weakening of the action of bacteriophage and the persistence of living bacteria in purulent lesions treated with bacteriophage.

Colvin in 1932,<sup>10</sup> incidental to his observations on the inhibition of lysis by sterile pus, cerebrospinal fluid and serum, found that bacteriophage could be found in the lesion several days after its administration.

### SOURCE OF MATERIAL AND METHOD OF STUDY

During the course of our study we have worked with four potent staphylococcus bacteriophages obtained from d'Herelle and Rakietsen in New Haven;

from McNeal of the Post-Graduate Hospital, New York City; from Gratia in Brussels; and from Larkum of the Department of Public Health in Lansing, Michigan.

Our bacterial cultures were obtained from 110 patients with furuncles and carbuncles on their first visit to the Vanderbilt Clinic. If the lesion was draining, the exudate was collected on a swab, if not, a small amount of plain broth was injected into its center and reaspirated. This fluid was then cultivated for from three to five hours in plain broth. From the three- to five-hour growth in broth, four 5 c.c. tubes of plain broth were inoculated and to two of these tubes, 0.25 c.c. of bacteriophage was added. The other two tubes were kept as bacterial controls. One tube containing bacteriophage and one control were incubated at room temperature and one of each was incubated at body temperature for twenty-four hours. At the end of this time the tubes inoculated with bacteriophage were read for the degree of lysis and graded from 0 to 4+, the latter grade being assigned only to those tubes which were absolutely clear, comparison being made with the growth in the control tubes.

At the same time that the broth cultures were made, a drop from the control tube and a drop from the tube containing the culture and bacteriophage were smeared on the two halves of a sheep's blood agar plate. If the growth in the control tube at room temperature was less than the growth in the incubated control tube, it was filtered and the filtrate tested for the presence of spontaneous bacteriophage. Next day the plates were studied and the cultural characteristics of the colonies with and without bacteriophage were noted. If the colonies on the control half were rough or varied in size or shape or appeared "moth-eaten," spontaneous bacteriophage was suspected and searched for. When such cultures were found, transplants were made from these colonies into broth, grown at room temperature, filtered, and the filtrate was tested for lysis of the homologous and stock strains. In the more recent phases of our study, we have found spontaneous bacteriophage more often than we did at first because of greater care in the search.

At twenty-four, forty-eight, seventy-two, and ninety-six hours, after bacteriophage was given, cultures were again taken from the lesions and studied for the characteristics of the colonies and the susceptibility of the organisms to bacteriophage. Usually bacteriophage was given twenty-four hours after the first visit, the interval required to determine whether or not the bacteria were susceptible to bacteriophage.

## RESULTS

I. *The Classification of 110 Strains of Staphylococcus Obtained from a Series of Furuncles and Carbuncles.*—In the whole series of 110 cultures, hemolytic *Staphylococcus aureus* occurred 81 times. In some of these cases the hemolysis was slight and could be seen only on removal of the colonies. Nonhemolytic *Staphylococcus aureus* was found in 18, and a mixture of these two in 8. Hemolytic *Staphylococcus albus* was found in one lesion and non-hemolytic *Staphylococcus albus* in one. Hemolytic *Staphylococcus aureus* and nonhemolytic *Staphylococcus albus* were combined in one. The results may be seen in Table I.

II. *The Susceptibility of the Hemolytic and Nonhemolytic Strains of Staphylococcus to Bacteriophage.*—Table I shows that only three of the 110 strains tested were found to be resistant to the action of all of the bacteriophages. Certain of the strains were resistant to one or two, but susceptible to at least one of the bacteriophages which we used. Two of the resistant strains were hemolytic *Staphylococcus aureus* and the other was a nonhemolytic *Staphylococcus aureus*. Of the 81 cultures of hemolytic *Staphylococcus aureus*, 64 were completely lysed; 15 underwent partial lysis; and 2 were resistant. Of the 18 strains of nonhemolytic *Staphylococcus aureus*, 16 underwent complete lysis; one partial lysis; and one was resistant. Of the 8 mixed cultures with both hemolytic and nonhemolytic *Staphylococcus aureus*, complete lysis took place in 5 and partial lysis in 3. With the 3 remaining albus cultures, either alone or with *Staphylococcus aureus*, complete lysis was obtained. In our series, therefore, no difference was found between the hemolytic and nonhemolytic strains in their susceptibility to bacteriophage.

III. *Persistence of Bacteriophage in the Lesion.*—The persistence of the bacteriophage in the lesion was studied in 32 patients, as the opportunity afforded upon their return to the clinic after treatment. In some the search was made after twenty-four hours and in others it was made later. In a few it was made daily, but in most of the cases we desired to institute daily treatment and did not withhold it to study the duration of the bacteriophage following a single injection. These results are shown in Table II. In 20, cultures were taken twenty-four hours after the first administration of potent bacteriophage. As a general rule, these cultures displayed considerable degeneration of the colonies on the blood agar plate. Often only remnants of colonies were left, or the intact colonies varied in size and shape. However, only rarely did we find no growth at all on the plate. On only two occasions, cultures of the lesion twenty-four hours after administration of bacteriophage yielded no growth on the plate or in broth. At the time of these observations, we assumed that bacteriophage was responsible, but its presence was not definitely proved. Broth tubes inoculated with cultures taken twenty-four hours after the administration of bacteriophage usually did not show growth when incubated at room temperature, but gave abundant growth

TABLE II

THE PERSISTENCE OF BACTERIOPHAGE 24, 48, 72, AND 96 HOURS AFTER INJECTION INTO THE LESION CORRELATED WITH THE CLINICAL EVIDENCE OF BENEFIT FOLLOWING THE TREATMENT

| NUMBER   | 24 HR. | 48 HR. | 72 HR. | 96 HR. | CLINICAL EFFECT |
|----------|--------|--------|--------|--------|-----------------|

| 27       | 0      | 0      | 0      |        | No benefit      |
| 28       |        | 0      |        |        | Marked benefit  |
| 29       |        | 0      |        |        | No benefit      |
| 30       | 0      |        |        | 0      | No benefit      |
| 31       |        |        | +      |        | Marked benefit  |
| 32       | +      |        |        |        | Marked benefit  |
| Totals   | 20     | 18     | 8      | 6      |                 |
| Positive | 16     | 12     | 6      | 2      |                 |
| Negative | 4      | 6      | 2      | 4      |                 |

in the incubator, although occasionally secondary lysis took place. Filtrates made of the 20 cultures left at room temperature produced complete lysis of the original homologous organisms obtained from the lesion in 16 instances, demonstrating the presence of potent bacteriophage. These bacteriophages often produced lysis of heterologous strains as well. They remained polyvalent and did not become specific for the homologous strain by passage. There is evidence, then, both from the appearance of the blood plates and from the test of the filtrates incubated at room temperature, that bacteriophage may be present in the lesion in about 4 cases out of 5 at least twenty-four hours after a single injection, and that under its influence there is a change in the growth characteristics and morphology of the organisms.

Cultures were taken from 18 cases forty-eight hours after the injection of bacteriophage. In most of these cases the culture was not taken after the first injection of bacteriophage, but later in the course of treatment. Therefore these and later determinations of bacteriophage in the lesion are not as significant as the tests made after twenty-four hours. The characteristics of the colonies on the blood plates made at this interval differed from those taken after twenty-four hours. Usually only a few colonies were af-

fects while the rest were normal. Large areas of destruction in the colonies were seldom observed. Degeneration of the organisms was not seen when these colonies were smeared and stained. Moreover, in the tubes incubated at room temperature some growth of organisms occurred in a high percentage of cases. When these tubes were filtered, however, the lytic principle was obtained from 12 of the 18, although the potency of the bacteriophage was definitely diminished. Those incubated at 37° C. usually showed abundant growth of bacteria.

It must be concluded, then, that bacteriophage persisted in the lesions for forty-eight hours in a smaller percentage of the cases and had less potency than at twenty-four hours.

Bacteriophage persisted in the lesion in 6 out of 8 cases tested after seventy-two hours, and in 2 out of 6 tested after ninety-six hours. The colonies on the blood plates showed no evidence of the destructive action, but the bacteriophages were recovered from the filtrates of cultures incubated at room temperature. These bacteriophages frequently gave only partial lysis, however.

IV. *The Relationship of the Persistence of Bacteriophage in the Lesion to the Presence of Antiphage in the Blood.*—In 22 cases we tried to correlate the persistence of bacteriophage in the lesion with the presence of an inhibiting substance in the blood serum. In testing for the presence of this substance we employed Rosenthal's technic.<sup>11</sup> In some instances the antiphage tests were done with the homologous strain of bacteria and in other cases with stock strains (Table III). Indirect antiphage (supposed to render the bacteria resistant to the lytic action of the bacteriophage) was only detected in 3 cases, while the direct antiphage (supposed to directly neutralize the action of the bacteriophage) was present in 16. Of 10 cases in which the test was made with the homologous strain, 7 showed a direct antiphage in the blood, but in 6 of these cases bacteriophage was found in the lesion from twenty-four to ninety-six hours after injection. The other 3 cases showed no direct antiphage in the blood, and bacteriophage was found in the lesion.

Of 11 cases in which the test was made for indirect antiphage using the homologous strain, two showed the presence of antiphage in blood, but the bacteriophage was later found in the lesion in both cases. In 9 cases no antiphage was found, but in 2 of these no bacteriophage could be found in the lesion.

Of 11 cases in which the test was made for direct antiphage, using a heterologous strain, 9 showed the presence of antiphage in the blood and yet in 7 of these bacteriophage was found in the lesion. In the 2 cases in which no antiphage was found in the blood, bacteriophage was present in the lesion. In the same 11 cases when the test was made for indirect antiphage using a heterologous strain, one showed the presence of antiphage in the blood, but bacteriophage was found in the lesion after twenty-four hours, while in 2 cases in which no antiphage was found in the blood, no bacteriophage could be found in the lesion after twenty-four hours. In 8 cases no antiphage was demonstrated in the blood and bacteriophage persisted in the lesion.

TABLE III

THE PRESENCE OF A BACTERIOPHAGE-INHIBITING SUBSTANCE, "ANTIPLHAGE," IN THE BLOOD SERUM OF THE PATIENT CORRELATED WITH THE PERSISTENCE OF BACTERIOPHAGE IN THE WOUND FOLLOWING TREATMENT

| NO. | ANTIPLHAGE IN THE SERUM* |         |          | PERSISTENCE OF PHAGE IN THE LESION |          |          |

\*As determined by the Rosenthal technic.

V. *Transmission of Bacteriophage in the Patient from a Site Remote from the Lesion to the Lesion Itself.*—In 8 patients, satellite furuncles developed around the original lesion treated with bacteriophage. Attempts to isolate the bacteriophage from these new lesions failed. Again, 4 patients were given subcutaneous injections of large quantities of bacteriophage at a distance from the lesion and bacteriophage could only be isolated from one of the lesions twenty-four hours later. This bacteriophage was very weak, producing only 1+ lysis of the homologous organism, and it produced no lysis of two heterologous strains against which the injected bacteriophage had previously been effective. In this one case, no bacteriophage was evident in the lesion before the injection, so that we must presume that it had either been transmitted from the site of the injection or was spontaneously generated. With the exception of this one questionable instance, we have no evidence that bacteriophage can be transmitted within the body from a site distant from a skin lesion to the lesion itself.

VI. *Behavior of the Bacteria Which Survive in the Lesions Which Have Been Treated with Bacteriophage.*—Our experience has shown that the surviving progeny of a culture of hemolytic *Staphylococcus aureus* which has been lysed by bacteriophage but not entirely destroyed, produces nonhemolytic colonies when grown on blood agar plates. Usually the colonies at first become mixed, some being hemolytic and some nonhemolytic, but in a few instances in our series all of the colonies promptly became completely non-hemolytic. In vivo a similar change has occasionally been observed, but it required more prolonged contact of the bacteria with the bacteriophage. Of

23 cases studied, this transformation occurred in 7. In 5 of these, the hemolytic variety was replaced after one or more bacteriophage treatments by a mixture of the hemolytic and nonhemolytic strains. In another, the hemolytic strain was completely replaced by nonhemolytic organisms, while in the last case the culture yielded a mixture of hemolytic *Staphylococcus aureus* and nonhemolytic *Staphylococcus albus*. The possibility of contamination in this case is recognized.

We have never observed a transformation of the staphylococcus from nonhemolytic to hemolytic after lysis in the test tube by bacteriophage, but such a change was observed on three occasions in patients in the course of bacteriophage treatment. Two of these new strains became resistant to bacteriophage, whereas the original cultures were completely lysed before treatment began.

These cases also illustrate that bacteria may become resistant to the bacteriophage during treatment. Acquisition of resistance was observed in 6 out of 36 cases, and in 4 of these, cultures were taken as the lesions were healing. In 8 instances the bacteria became more susceptible to bacteriophage while in the remaining 22 cases no change in the susceptibility of the bacteria to the bacteriophage took place.

It was also observed, after bacteriophage had been injected into the lesion, that the colonies frequently changed from smooth to rough. Moreover, some of the colonies became pinpoint. No further changes than these could be detected in their characteristics as healing progressed in the presence of bacteriophage, except that some of the colonies from the larger carbuncles changed in color from yellow to white.

At no time could we surely demonstrate a complete destruction of bacteria in the lesion tested with repeated injections of bacteriophage. They persisted even after the slough and pus had disappeared. On several occasions, moreover, positive cultures were obtained after the removal of the terminal scab.

Bacteria also persisted in 7 lesions in which bacteriophage was generated spontaneously. These cultures showed considerable degeneration, however, and many of the colonies were roughened. All of the bacteriophages isolated from these lesions were polyvalent and possessed considerable potency.

From our results, therefore, we can only conclude that while the bacteriophage may change the characteristics of the bacteria in the lesion, it certainly does not completely destroy them.

VII. *The Correlation of Various Laboratory Findings With the Clinical Results.*—Untreated furuncles and carbuncles run a varied course under the variable conditions found in different individuals. Furuncles tend to be self-limited. There is a period of induration, a period of liquefaction and discharge, and a period of resolution. The same periods are more prolonged in carbuncles. The extent of the slough, the rapidity of liquefaction, and the size and number of the drainage openings all modify the period of spontaneous healing. With such variable controls it is very difficult to judge in any given cases whether or not any form of treatment hastens or delays the process of

healing. In order to furnish convincing evidence, we must await the acquisition of a large series of treated cases with an exactly parallel series of controls, unless we can apply a clear-cut laboratory criterion. This we are trying to establish. For the present we have tried to note from the appearance of the lesion after treatment, as well as from the subjective symptoms of the patient, whether or not the progress of the infection indicated a favorable or an indifferent effect from the bacteriophage treatment. (In no case have we had an unfavorable reaction.) We have tried to discover whether this could be correlated with (a) the presence of a bacteriophage-inhibiting substance, "antiphage," in the blood, or (b) the persistence of bacteriophage in the lesion, or (c) the maintenance of susceptibility to the bacteriophage on the part of the invading organism, or (d) changes in the hemolytic action of the cultures on blood agar.

(a) *Antiphage*: In 34 cases a study was made of the presence of antiphage in the blood with the Rosenthal technic,<sup>11</sup> and the tests were carried out with the homologous organisms (see Table IV). Eight of these cases gave evidence of the presence of both strong direct and strong indirect antiphage. After instituting bacteriophage treatment, our belief was that the bacteriophage had exerted a favorable influence in 5 of these and had had no influence on the infection in 3. Seven of the cases gave a strongly positive test for direct and a negative test for indirect antiphage. Of these, 5 gave a favorable response to bacteriophage, while 2 seemed to be slightly improved by it. Eight of the cases gave evidence of a weak direct antiphage and no sign of indirect antiphage in the blood; and of these, 5 gave a favorable response and 2 a questionable response, while one was not affected. Five cases gave no evidence of direct or indirect antiphage. Of these, 2 were favorably affected and 3 gave a questionable response. The other groups are too small to be significant.

\*As determined by Rosenthal's technic.

(b) *Persistence of Bacteriophage in the Lesion* (see Table II): In the 32 cases in which the bacteriophage was sought for, twenty-four to ninety-six hours after its injection into the lesion, 16 cases out of 20 tested showed the bacteriophage in twenty-four hours. Of these, 14 gave a very favorable re-

sponse while 2 were slightly favorable. Of 4 cases which yielded no bacteriophage after twenty-four hours, one seemed to be favorably affected by the treatment while 3 were unaffected. The favorable case had already completely liquefied when treatment began. In forty-eight hours, 18 cases were tested for the persistence of bacteriophage. Twelve of these cases showed bacteriophage in the lesion at that time. Seven of them responded very favorably, while in 5 the effect was slightly favorable. Of 6 cases which showed no bacteriophage after forty-eight hours, 2 seemed to respond well after bacteriophage treatment, while 4 gave no evidence of any favorable response. One of the favorable cases had already liquefied. Out of 8 cases tested after seventy-two hours, bacteriophage was found in 6 and all seemed to be benefited by the bacteriophage treatment. In the 2 cases in which no bacteriophage was found after seventy-two hours, one seemed to be favorably affected by bacteriophage treatment while the other was not. In the favorable case, bacteriophage had been found in twenty-four hours. In 6 cases bacteriophage was sought for, ninety-six hours after its injection. It was found in 2 cases only. In 3 others it had been present at twenty-four, forty-eight, or seventy-two hours. In all of these cases, the result was favorable. In the other case in which it was not found, it had also been absent at forty-eight hours. In this case the effect of bacteriophage was negligible.

(c) *Maintenance of Susceptibility of the Bacteriophage on the Part of the Culture:* After treatment with bacteriophage, as we have stated above, the organism cultured from the lesion may show an increased or decreased susceptibility to the bacteriophage. This observation was correlated with the clinical response in twenty-eight cases (see Table V). In 25 of these cases the organism remained susceptible to the bacteriophage. Of these, 20 gave a favorable response while 5 were not benefited. In 2 cases the organism was only partially susceptible and these cases were not benefited. In 3 cases the organism became resistant to the bacteriophage and none of these was helped by the bacteriophage treatment.

TABLE V

THE MAINTENANCE OF SUSCEPTIBILITY TO PHAGE ON THE PART OF THE CULTURE CORRELATED WITH THE CLINICAL EFFECT OF BACTERIOPHAGE TREATMENT

|                      | NO. OF<br>CASES | CLINICAL EFFECT OF PHAGE<br>TREATMENT |            |
|----------------------|-----------------|---------------------------------------|------------|
|                      |                 | BENEFITED                             | NO BENEFIT |
| Remained susceptible | 25              | 20                                    | 5          |
| Became resistant     | 3               | 0                                     | 3          |

(d) *The Changes in the Hemolytic Action of the Culture on Blood Agar:* We have stated above that when hemolytic *Staphylococcus aureus* is lysed by bacteriophage in the test tube, if it is not entirely destroyed, the progeny are generally nonhemolytic. These bacteria are evidently resistant to the lytic effect of the bacteriophage. In treated cases these forms often appear, but not as regularly as in the test tube. The clinical result in these cases is not as favorable as in those in which the organism, which is recovered from

the lesion after treatment, is the same as it was before treatment whether it were hemolytic or nonhemolytic. In thirty-four cases in which this point was studied, 22 showed no change in the culture and the clinical results were favorable in 18 and indifferent in 4. In the other 12 cases there was some modification of the culture, consisting of a change either in the hemolytic or chromogenic function of the organism. In 4 of these the results were favor-

TABLE VI

CHANGES IN THE CULTURAL CHARACTERISTICS OF THE BACTERIAL STRAINS FOLLOWING BACTERIOPHAGE TREATMENT CORRELATED WITH THE CLINICAL RESULTS

|                      | NO. OF<br>CASES | CLINICAL EFFECT OF PHAGE TREATMENT |                   |               |
|----------------------|-----------------|------------------------------------|-------------------|---------------|
|                      |                 | BENEFITED                          | SLIGHT<br>BENEFIT | NO<br>BENEFIT |

| Change in culture    | 12              | 4                                  | 2                 | 6             |

able, in two there was partial success, either favorable at first and later indifferent, or indifferent at first and later favorable, while in 6 there was no apparent response to the treatment (see Table VI).

#### DISCUSSION

We recognize the difficulty of judging whether or not the administration of bacteriophage affects in any way the course of the disease. In order to be thoroughly convinced by clinical criteria alone, we should have two absolutely parallel series, one treated with bacteriophage and one untreated. We are at present attempting to assemble two such parallel series, taking into account the age of the lesion, its location, the presence and degree of necrosis, and the size of the lesion at the time of the beginning of treatment. If the results in these treated cases can be correlated with certain consistent laboratory findings, the latter may be depended upon as bases for prognosis.

It has been observed repeatedly that the most severe staphylococcus infections generally yield on culture a hemolytic strain of *Staphylococcus aureus*. Lesions somewhat less severe may yield a culture showing no hemolysis or a very slight degree of hemolysis beneath a few colonies on a blood plate. Still less severe lesions more often yield *Staphylococcus albus* rather than *S. aureus*. In our series the primary cultures yielded the usual proportion of such variable strains. The cultures which we called a mixture of hemolytic and nonhemolytic *Staphylococcus aureus* may have been pure cultures of the intermediate group, but usually those showing frankly yellow and frankly white colonies do represent a mixture of aureus and albus. It is rather surprising that in lesions of this kind mixtures are not more frequently found.

In our studies the hemolytic and nonhemolytic strains showed an equal susceptibility to the bacteriophages which we employed. Attention must be called to the fact, however, that our organisms were freshly isolated from acute staphylococcus infections and the same results might not have been obtained with staphylococci obtained from chronic infections or with cultures grown for some time in artificial media. Thus we did not confirm the observations of either d'Herelle and Rakieten or McKinley and Camara whose results

were opposed to one another. Differences in results could probably be explained by differences in the bacteriophages employed. This point does not seem to be important. There does seem to be some significance, however, in the fact that both in the test tube and in the patient the organisms undergo certain changes after contact with the bacteriophage. The hemolytic strains frequently become nonhemolytic, the smooth strains tend to become rough, and while they may become more resistant to the lytic action of the bacteriophage, both of these changes are in the direction of nonvirulence. It should be remembered that this occurred more consistently in the test tube than in the patient, but such changes occurring in the lesion might favor the prompt recovery from the infection by the action of the defensive forces of the body.

The persistence of the bacteriophage for twenty-four hours or more in the lesion after one injection is of considerable importance from a practical viewpoint. We do not feel that there is any evidence that it actually propagates itself there, and when injected elsewhere what may appear in the lesion gives no evidence of increasing either in quantity or in potency. In the lesion evidently something inhibits the multiplication of the bacteriophage, and yet it is not due to the presence of any inhibiting substance in the patient's serum, if Rosenthal's method can be relied upon, for the failure of the bacteriophage to persist in the lesion does not run parallel with the presence of such a substance in the blood as shown by this test. If Rosenthal and Raiga obtained better results in their cases by autohemotherapy it is hard to believe that this fact is due to any alteration of this substance in the blood. The failure to corroborate their results has induced us to study this phase of the problem more fully. The failure of the bacteriophage, recovered from the wound either after twenty-four or forty-eight hours, to act at incubator temperature would seem to indicate that it is less potent than the original bacteriophage, and it is, therefore, overwhelmed by the growth of the organisms at the temperature most suitable for their propagation. This temperature is, of course, the temperature at which bacteria grow in the body, and therefore, the inaction of the bacteriophage at body temperature may be of some significance.

The weakening of the bacteriophage by its habitation in the lesion for twenty-four hours was also indicated by the development of secondary growth after lysis. With the potent bacteriophages originally employed, secondary culture formation seldom occurred, but with the bacteriophages obtained from the lesion, either those arising spontaneously or those persisting for a day or two after instillation, secondary growth was the rule.

All of these results fail to support the idea that the bacteriophage propagates itself in the lesion. This points to the necessity of frequent reinoculations of the bacteriophage into the lesion. If bacteriophage is not reinjected into the lesion, at the end of twenty-four hours the growth of bacteria untouched by the original injection may continue unabated. These facts need further elucidation, but in the meantime there is a very definite indication for the frequently repeated administration of large quantities of bacteriophage, if it is to be used at all. Until we know what is inhibiting its propa-

gation in the body or in the lesion we must expect very little action following its injection at a distance from the lesion, except whatever may be gained from the injection of the lytic products of the bacteria.

In attempting to correlate the clinical results with certain laboratory findings, it would appear from the above observations that the presence or absence of antiphage in the blood as determined by Rosenthal's method has little or no effect on the usefulness of bacteriophage treatment. This point will be studied further and enlarged upon in another paper. However, the persistence of bacteriophage in the lesion and the persistence of susceptibility of the culture to the bacteriophage, as well as the absence of the development of progeny having cultural characteristics different from the original culture, are all factors of considerable importance. These three may all be important because they may indicate the potency of the bacteriophage. If there can be any other simple laboratory method of determining the potency of bacteriophage and maintaining its potency, the problem will be greatly simplified. But the efficiency of any treatment is determined to a great degree by the phase of the disease in which the treatment is begun. This is particularly true of infections for even after the infection is under control the process of healing is greatly modified by the kind and extent of the tissues which have been destroyed.

#### SUMMARY

One hundred and ten cases of furuncles and carbuncles have been studied from the point of view of the cultural characteristics of the strains of staphylococcus obtained from them and the susceptibility of those strains to the lytic action of bacteriophage as well as the changes in the cultural characteristics of these strains both in the test tube and in the lesion following the repeated administration of the bacteriophage. Certain features of the behavior of the bacteriophage and its persistence in the lesion have also been studied, and an attempt has been made to correlate the persistence of the bacteriophage or the disappearance of it in the lesion with the absence or presence of an inhibiting substance in the patient's serum known as antiphage. Our findings were briefly as follows:

1. A relationship could not be demonstrated between the hemolytic or nonhemolytic properties of the staphylococci and their susceptibility to bacteriophage. Of the 110 strains tested, only three were resistant. In the whole series, 81 were hemolytic *Staphylococcus aureus* and 18 were nonhemolytic *Staphylococcus aureus*. The rest were intermediate or mixed strains. These tests were all made with freshly isolated strains of bacteria and with several potent bacteriophages. The results indicate that if potent bacteriophages are employed practically all strains of staphylococci from acute lesions can be lysed.

2. The bacteria in the lesions were found to be altered in their cultural characteristics following the repeated injections of bacteriophage. After twenty-four hours the colonies on the blood plates showed degenerative changes, areas of absent growth, and "a moth-eaten appearance." At forty-eight hours these changes were not as marked, although after more injections, the colonies sometimes became roughened and pinpoint in size. A few

changed in their chromogenic properties and some in their hemolytic properties. Some became more resistant to bacteriophage and still others less resistant. In the majority of instances, the cultures remained unchanged in their susceptibility to bacteriophage. It was seldom demonstrated that the lesions became absolutely free of bacteria either after repeated injections of bacteriophage or when the bacteriophage was generated spontaneously in the lesion, although in two cases negative cultures were obtained both on the plate and in broth. This may have been due to inhibition by bacteriophage rather than actual destruction, for subsequent cultures were positive.

3. After one injection of bacteriophage, the lytic principle could be re-isolated from the lesion at the end of twenty-four hours and forty-eight hours. At these intervals the bacteria showed evidence of destruction, particularly at the twenty-four-hour period. The bacteriophage could also be recovered from the filtrate of cultures incubated at room temperature after seventy-two and ninety-six hours, after instillation into the lesion, but in a much weakened state. While the bacteriophage persisted in the lesion and still had some destructive action after twenty-four hours, it did not increase in potency as it did in the test tube. Instead, it grew progressively weaker.

4. In about a third of these cases, the serum of the patients was tested for the presence of "antiphage," a substance which has the power to inhibit the action of bacteriophage in the test tube. This principle was found in the blood serum of a number of these patients, but there was no correlation between this fact and the persistence or disappearance of bacteriophage in the lesion.

5. The favorable clinical effect of the use of bacteriophage seems to have some correlation with the persistence of bacteriophage in the lesion and the maintenance of the cultural characteristics and susceptibility of the strain producing the disease and may have little or nothing to do with the presence or absence of the so-called "antiphage" (bacteriophage inhibiting substance) in the blood serum of the patient.

# CORONARY OCCLUSION AND SUDDEN DEATH

A STUDY BASED UPON A REVIEW OF 345 NECROPSIES PERFORMED AT THE BOARD OF HEALTH LABORATORY, ANCON, CANAL ZONE, BETWEEN APRIL 15, 1932, AND APRIL 15, 1933

CAPT. ELBERT DECOURSEY, M.C., U. S. ARMY, ANCON, C. Z.

## HISTORY

CORONARY occlusion was recognized and described at autopsy by pathologists forty to fifty years before wide medical interest was aroused in the disease about 1918. Coronary disease "has only been generally recognized and found to be extremely common since about 1926," according to Rolleston,<sup>1</sup> who also states that the condition was first described adequately by Weigert in 1880, but that a clinical diagnosis of coronary thrombosis was made in 1876 by Adam Hammer. In a general review, Benson<sup>2</sup> traces first observations on coronary sclerosis to Drelinecourt in 1700. Dock recognized the disease during life in one patient, and in 1896 reported the case with autopsy confirmation.<sup>3</sup> In 1910, in Germany, two Russians, Obrastzow and Straseshesko<sup>4</sup> adequately described the clinical syndrome. Herrick<sup>5</sup> soon described the disease in America. Osler<sup>6</sup> early correlated the clinical and pathologic findings; he believed that the disease was one which affected mainly the upper classes, and he used as examples, John Hunter, Charcot, Nothnagel, and William Pepper, each of whom died of coronary disease.

## CASE REPORTS

There are a few general considerations to be mentioned before reviewing the cases listed in Table I. A constriction of 95 per cent or more of the arterial lumen is considered as occlusion in this paper. All autopsies were performed within twenty-four hours postmortem, and included examination of the brain, microscopic examination of all organs, and except in embalmed bodies, serologic and chemical examination of the blood and spinal fluid. In the embalmed bodies fixing fluid generally was flowing into the right common carotid artery within three hours after death. Cases 1 to 11, inclusive, are of coronary sclerosis; Cases 12 to 15, inclusive, are of coronary sclerosis with thrombosis; Cases 16 and 17 are of constriction of the coronary orifice by syphilitic aortitis; and Case 18 is of coronary embolism from a mitral valve vegetation.

## DISCUSSION

*Age.*—As shown in Table II, the fifth and sixth decades claimed the most cases. This frequency is one decade younger than the usual published figures,

\*From the Board of Health Laboratory.

Received for publication, December 23, 1933.

Read before the Medical Association of the Isthmian Canal Zone, July 18, 1933.

and may be explained by the relatively younger ages of the inhabitants of the Zone. However, this is not a disease of the aged as shown by Conner and Holt,<sup>7</sup> who in a study of 287 cases found that initial symptoms occurred before fifty-one years of age in 33 per cent and before sixty-one years of age in 75 per cent. According to Eggleston<sup>3</sup> the disease is rare before forty, not uncommon between forty and fifty, and most frequent between fifty and seventy. The ages of the embolic and of the syphilitic constriction of the orifice cases may be much younger. The age of a black female who recently died suddenly from syphilitic atresia of the left coronary orifice was sixteen years.

*Sex.*—There were many more males (87.5 per cent) than females (12.5 per cent), and since in the Canal Zone all cases of sudden death are sent to the morgue for autopsy these figures probably represent the existing situation. Published series show a variation from about 10 to 30 per cent in the number of females affected.

*Race.*—Although in autopsies on 286 bodies over one year of age only 78 were white, the number of coronary sclerosis deaths was exactly twice as numerous in the white as in the black race. Considering all types of coronary occlusion there was a marked preponderance in the white race, the usual finding.

*Symptoms.*—The symptoms are best demonstrated by the four hospitalized cases (2, 8, 10 and 14), three of which showed sclerosis only and one of which showed sclerosis with thrombosis. Dyspnea occurred in all four cases. Cardiac pain, gastric symptoms (of nausea, vomiting, or epigastric discomfort), fever (because of the profuse sweating the oral temperature reading may be below normal, but a rectal temperature reading will generally indicate the presence of fever) and/or cough occurred in three. In two cases tachycardia, low blood pressure and leucocytosis were found. Enlarged heart, pericardial friction rub, and albuminuria were found once. The electrocardiogram was used once and correctly aided in the diagnosis. It is interesting to note that in a study of coronary occlusion at Peter Bent Brigham Hospital in 1923, Wearn<sup>8</sup> stated that there was "no typical or characteristic electrocardiographic curve of the condition." The clinical symptoms are due to the ischemic necrosis of the myocardium and they are well described in the literature,<sup>9</sup> and in recent textbooks. Hamman<sup>10</sup> has collected the symptoms into four groups based upon the pathologic changes, as follows: (1) The immediate symptoms associated with the lesion, the anginal seizure; namely, pain and shock manifested by prostration, fall in blood pressure, and suppression of urine; (2) the symptoms associated with the myocardial change; namely, dyspnea, feeble cardiac impulse, and chronic passive congestion manifested by cyanosis, pulmonary edema, enlarged liver, and albuminuria; (3) the symptoms associated with myocardial infarction; namely, fever and leucocytosis, pericarditis, and embolic phenomena; and (4) additional symptoms such as gastric, vasomotor and nervous.

The longest duration of symptoms before death in sclerosis was three and one-half years (Case 2), and then the patient died suddenly. One patient had symptoms for six months; 2 had symptoms for two months; and 2 had some previous but slight symptoms. In 3 the duration of symptoms is unknown. Since the mortality of the first attack is only about 16 per cent,<sup>7</sup> prompt recogni-

tion is an advantage for earlier and prolonged rest treatment and a better functional outlook.

*Pathology.*—Unfortunately “coronary thrombosis and infarction of the heart are generally spoken of in the same breath as if they were one and the same thing,”<sup>12</sup> whereas ischemic necrosis of the myocardium may result from only an extreme degree of narrowing of the coronary arteries, a lesion too seldom stressed in the literature. That “the obstruction is almost always due to the development of a thrombus”<sup>13</sup> is not borne out by postmortem findings (Boyd,<sup>12</sup> Willius,<sup>13</sup> and Bedford<sup>14</sup>). The clinical use of the term “Coronary Occlusion, due to . . . (type of lesion)” is suggested.

In every case of sclerosis with or without thrombosis the occlusion was in the left coronary artery, and in only one case was it not in the anterior descending branch. The typical location for the largest atheromatous patch was from 2 to 3 cm. beyond the bifurcation of the main artery. In coronary disease the statistical evidence is in favor of a diagnosis of left coronary occlusion unless there is some definite evidence for right coronary occlusion, such as emboli in the lungs from a mural thrombus in the right ventricle. The right coronary artery was the seat of the lesion only in the case of embolism. The left coronary was the seat of the lesion in 16 of Wearn's 19 cases. Of 33 cases with autopsy, Willius<sup>13</sup> found the left coronary artery occluded in 29, the right in 2, and both in 2.

The areas of ischemic necrosis generally appeared in the anterior portion of the left ventricle near the apex; in four cases they also appeared in the left side of the interventricular septum. Although in 10 cases there were distinct gross acute infarcts, in only 3 of them were there conspicuous white infarcts. It is necessary to closely inspect the myocardium because “acute infarct formation may frequently be overlooked in the gross specimen.”<sup>14</sup> Ischemic necrosis was evident in every case microscopically. Such a heart embalmed immediately after death presents an easily discernible infarct which is characterized by a pink area of softness (devoid of arterial supply) surrounded by firm, fixed myocardium; postmortem blood clotting which has occurred before embalming may

obstruct a coronary artery and the surrounding myocardium may simulate an antemortem infarct, but then the microscopic picture of swollen muscle cells with granulation, loss of striation, shrunken nuclei, leucocytic infiltration and of a bordering zone of hyperemia is absent. An infarct which extends to the endocardium offers an opportunity for the formation of a mural thrombus (only one, Case 14, in this series) and resulting emboli, or, the infarct may extend to the pericardium and bring about a pericarditis. An infarct may become thin, form a myocardial aneurysm, and finally rupture. Myofibrosis, evidence of previous anemia, was found in all cases except the one of embolic occlusion. Generalized arteriosclerosis was found in 14 cases; and in 2 cases syphilis may have been the etiology of the sclerosis. An enlarged liver (1,750 gm. or over) occurred in only 50 per cent, a low figure. Albuminuria was present in 66 per cent of the cases in which urinalysis was done. Extracardial thrombi were found in only 2 cases. Meakins<sup>11</sup> in 62 cases of coronary artery thrombosis found extracardial thrombi in 40 cases.

*Sudden Death.*—Excepting the accidental and traumatic deaths there were 25 sudden deaths from all causes. Table III shows the various causes with age, sex, and race figures. Cerebral hemorrhage is a clinical diagnosis commonly made at sudden death. Death from cerebral hemorrhage occurred in only 3 cases within twenty-four, twenty-three, and fourteen hours, respectively, after the strokes. "Of all sudden and unexpected deaths, apoplexy furnishes the fewest autopsies and inquests."<sup>15</sup> The largest single cause was coronary occlusion, which was more frequent than all other causes combined. It is interesting to note that of 11 cases of sudden death in the white race, 8 were of coronary occlusion. Table IV shows the various types of coronary artery occlusion which caused sudden death. Major McNabb,<sup>16</sup> in reviewing the 348 autopsies he performed in a year at the Canal Zone Board of Health Laboratory, found 14 cases of sudden death caused by coronary occlusion, and that "60 per cent of sudden deaths were a result of myocardial failure resulting from coronary lesions." In

a recent study of 198 patients brought in dead, Bedford<sup>14</sup> found "coronary artery disease, 80 cases, and atheroma of coronary arteries, 63 cases."

Scott<sup>17</sup> has aptly said "when a man beyond forty and in his usual health is seized with a severe attack of substernal pain, accompanied by shock, circulatory collapse, and dyspnea, we may assume that something definite has happened in the heart. If the patient dies in a few minutes, we may be reasonably sure that he has had a circulatory accident, most likely coronary. Indeed, more than 90 per cent of all individuals dying suddenly . . . will show at autopsy a cardiac lesion, coronary disease . . . or rupture of the heart at the site of an old or recent infarct. In a few cases a ruptured aorta is found. Very rarely does cerebral hemorrhage kill in a few minutes. In spite of these well-established facts we still find such erroneous diagnoses as 'acute indigestion,' or 'ptomaine poisoning' given as the cause of sudden death."

#### SUMMARY

In a study of 345 consecutive autopsies, of which 286 were upon bodies over one year of age, representing 208 negroes and 78 Caucasians, and which were performed one calendar year, there are presented: 18 cases of coronary occlusion produced by sclerosis without thrombosis (11), sclerosis with thrombosis (4), syphilitic constriction of a coronary artery orifice (2), and embolic occlusion (1); a discussion of the symptoms and pathology of coronary occlusion; and a discussion of 25 cases of sudden death, 13 of which were caused by coronary occlusion.

It is suggested that the inaccurate general term "coronary thrombosis" be used only when an actual thrombus is present.

The following *working rule* is suggested: *Unless there are signs definitely indicating other disease in a white male over forty years of age who dies within three hours after the onset of either respiratory, cardiac, or gastric symptoms, the cause of death is coronary occlusion.*

## ALPHA DINITROPHENOL AND ITS INFLUENCE UPON METABOLISM\*

WILLIAM EGBERT ROBERTSON, M.D., F.A.C.P., PHILADELPHIA, PA.

MY INTEREST in this chemical substance was aroused during the Great War. The reports of cases of acute and others of chronic intoxication; the circulatory disturbances in the former and the progressive loss of flesh, anemia, and sweating in the latter, and even sudden death among some of the acute manifestations, naturally invited attention in relation to the manufacture of munitions, especially during that period when part of this industry devolved upon the United States. When the pernicious potentialities of certain of the chemicals utilized in the making of explosives were clearly recognized, successful methods of safeguarding those in the industry were introduced. It was this factor probably which caused a lag in the attention originally given to the subject. However, during the past two years especially, numerous articles have appeared, most of them in the French journals, particularly by pharmacologists and physiologists. Most of the published work has dealt with the effects of nitrated naphthols, specifically dinitro-alpha-naphthol, often referred to for the sake of brevity as D. A. N. Of the two isomers, alpha and beta-naphthol, the nitrated alpha-naphthol has received the greater attention. These two are derived from coal tar, or are prepared synthetically by hydrating the hydrocarbon naphthalene. The phenol group consists of nitrated hydroxyl derivatives of benzene. Both the naphthol and phenol groups are toxic in certain doses. Both are thermogenic, also in appropriate doses, but the naphthol group is more selective in its thermogenic properties, for certain animals fail to develop fever, irrespective of the route by which the drug is administered.

Renewed and widespread interest has been stimulated by the recent article by Cutting, Mehrtens and Tainter,<sup>1</sup> and still more recently by the publications of Anderson, Reed and Emerson<sup>2</sup> and by Tainter, Stockton and Cutting.<sup>3</sup> Each of these reports dealt with alpha-dinitrophenol (1:2:4), and, as the Preliminary Report of the Council<sup>4</sup> stated, "this compound is relatively new both to pharmacology and to clinical medicine." To those who know something of the literature of this subject, and particularly if they have had some clinical experience with this chemical, the advice of the Council will be regarded as sound. "There are limitations to and possible dangers from the use of the drug clinically. It should be used only under strictly controlled conditions." Pertinent to this quotation, it may be stated that the dose should be accurate, based upon the weight of the patient, and converting metric into apothecary's weight may introduce a possible error. I seriously question

\*From the Medical and Metabolic Departments of The Philadelphia General Hospital.  
Received for publication, December 28, 1933.

whether any prescription receives the calm and dispassionate attention it deserves, in the delicatessen and lunch counter drug store. Perhaps the abolition of the Eighteenth Amendment may aid in restoring that which has come to be spoken of as the older type of drug store.

In an editorial comment<sup>2</sup> on dinitrophenol, the writer raises the question as to whether there are cumulative effects from small doses repeated over long periods. To this it may be said that the drug has been given over a period of months with no appreciable ill effects. In doses over 10 mg. per kilo it will produce profuse, drenching sweats, fever, and very high metabolic rates. In the doses generally employed, 3 to 5 mg. per kilo, there is rarely even a slight elevation of temperature as measured by the clinical thermometer, no increase in heart rate, sweating is not always marked, but the metabolic rate begins to rise soon after the drug is taken, but falls to the patient's normal again in about forty-eight hours. The increased metabolic rate is not maintained after stopping the drug, even in those to whom it has been given over long periods of time. There is no proof therefore, based upon the specific action of the drug, that cumulative effects occur. Eruptions have been reported and edema, especially from the sodium salt which is much more soluble than the acid. Whether other idiosyncrasies exist, or whether it will manifest any ill effects in the presence of infections or disturbed metabolic states, cannot be stated definitely at this time. Both from animal experimental work, using nitrated naphthols, and from the clinical use of alpha dinitrophenol, it is fairly evident that these compounds should not be used in diabetes or in any phase of hyperthyroidism. Owing to the rapidity with which the average obese individual passes "from hand to mouth" so to speak, the difficulty in controlling diets, even in the hospital ward, in the absence of a well-organized metabolic department, and the almost uniform rapidity with which dinitrophenol speeds up metabolic rate, the chief interest seems to center in the possibility of weight reduction without detailed and specific supervision of the dietary. With this in view therefore, I solicited the cooperation of the metabolic department of the Philadelphia General Hospital, under the directorship of Dr. Edw. S. Dillon, Dr. W. G. Karr the metabolic chemist of the department, and Mr. Theodore V. Letonoff, assistant metabolic chemist.

The patient, J. S., a male, aged fifty-six, a chauffeur, was admitted to my ward on July 18, 1933. He complained of swelling and soreness of his ankles, of pain in various parts of his trunk and limbs, and that his excessive weight and dyspnea prevented him from working. Decidedly short, his average weight had been 168 to 170 pounds for some years. Nineteen months prior to his admission to hospital, he had reached 200 pounds. This remained fairly constant until seven months ago, when he began to gain more rapidly and went up to 245 pounds. Unable to work, probably economic conditions brought about a reduction in weight, for he was 214 pounds when first seen. He was not only obese, but he had in addition a nodular, circumscribed lipomatosis on limbs, thorax, and abdomen. As is not unusual, many of these areas were tender, he was subject to neuralgic pain, tired easily, a syndrome characteristic of adiposis

dolorosa and not unusual in the nodular, circumscribed variety. This nodular distribution he first noted thirty years ago and gradually the tumefactions increased in number, a few having become quite large. His bowels were regular, his habits good. He denied the use of alcohol. No syphilitic history, Kahn negative. Family history of no importance. His past history was good, but for a postnasal catarrh for some years and moderate deafness, especially in the right ear, which followed a severe cold ten years ago. For some months he had a productive cough and an occasional night sweat.

*Physical Examination.*—Not of pituitary type. No abnormal distribution of hair. Teeth in poor condition. A little pyorrhea. Tonsils enlarged. Few râles at bases of lungs. Heart: 13 cm. from midline to left border. No murmur. Muscle tone suppressed and distant. Pulse rate 80. Blood pressure, 142 systolic; 90 diastolic. Abdomen: No gross pathology noted. Genitalia: normal. Eyes: Pupils reacted normally to light. Veins overfull. No pathologic findings on examination of fields. Skull: X-ray of bones of skull was negative. No evidence of intracranial pressure. Sella slightly larger in vertical diameter than normal. A narrow bridge of bone passed from the anterior to the posterior clinoid, but the clinoids were otherwise normal. One of the circumscribed, fatty masses was removed for a biopsy. Dr. R. P. Custer reported the finding of typical adult fat supported by the usual fibrous trabeculae.

Before any of the drug was given to him, he had a basal metabolism rate of plus 6 on one occasion, plus 8 on another. His blood counts and urine were normal. Blood cholesterol 270, and his calcium 12.6 and 10.3 at different times. Liver function by the bromsulphaline and by the Quick, benzoic acid methods were both normal. Without dietary restriction, limiting fluid to 1,500 c.c. daily, he lost four pounds in nine days, his weight now being 210 pounds on July 27, 1933. On Aug. 9, 1933, he was placed upon a diet of

| Proteins | Fats | Carbohydrates | Calories |
|----------|------|---------------|----------|
| 100      | 50   | 100           | 1,250    |

Fifteen days later, on Aug. 24, 1933, he weighed 205 pounds, a total loss of but 9 pounds in thirty-seven days, approximately  $\frac{1}{4}$  of a pound a day. On Sept. 18, 1933, he was admitted to the men's metabolic ward and the metabolic study was begun. At this time he weighed 197 pounds, a total loss of 17 pounds in sixty-two days, a little over  $\frac{1}{3}$  of a pound a day since his admission to the hospital. Up to this date he had received no dinitrophenol and during this period his basal metabolism rate was plus 6 on July 27, 1933, and plus 8 on Aug. 24, 1933. On Sept. 18, 1933, his fasting blood sugar was 100; Urea N. 0.013; CO<sub>2</sub>, 59 vol. per cent. For the next three days he was kept upon the following diet:

| Proteins | Fats | Carbohydrates | Calories |
|----------|------|---------------|----------|
| 100      | 50   | 100           | 1,250    |

Sept. 22, 1933, his diet was changed as follows:

|          |      |               |          |
|----------|------|---------------|----------|
| Proteins | Fats | Carbohydrates | Calories |
| 85       | 60   | 200           | 1,680    |

## Sugar Tolerance

|                    |         |
|--------------------|---------|
| Fasting            | 83 mg.  |
| $\frac{1}{2}$ hour | 132 mg. |
| 1 hour             | 134 mg. |
| 2 hours            | 90 mg.  |
| 3 hours            | 61 mg.  |

It will be noted that from Sept. 18 to Oct. 3, 1933, a total of fifteen days, he lost an additional four pounds in weight, or approximately one-quarter pound per day. Following his return to the medical ward, he was not given dinitrophenol for a couple of days, hence his return to a basal metabolic rate of plus 7, with a respiratory quotient of 0.76. The dose of 0.45 gm. given at one time on September 25 and 26, the first two days of the observation, was equivalent to 5 mg. per kilo. The same dose was given on September 28, but on September 27 the dose was less, being but 4 mg. per kilo. Despite the smaller dose on this day, the basal metabolism rate rose to plus

72, very much higher than it had done on September 25 and 26, which were fasting periods. We interpreted this as being due to the specific dynamic action of the food, plus the elevation of rate due to the drug. It will be evident, therefore, that in the ambulatory individual on a full diet, even smaller doses should be employed. One woman who was on a full diet and ambulatory, except during the period of study of her rates, with a basal rate of minus 27, was given but 1 mg. per kilo. One hour later her rate was minus 22, and after another hour it was minus 13. In none of the various observations above cited was there any appreciable change in temperature and pulse or respiration. On another occasion, I intend to present other phases of this subject, but at this moment my chief concern is to advocate a small dose once a day of 3 mg. per kilo, or even better, but 2 mg. per kilo over a long period of time, to the obese individual who is not a diabetic, and is engaged in a daily routine, i.e., not bedridden. This I regard as perfectly safe. Weight will not be lost rapidly and many days may elapse after the drug is first given before the weight begins to fall, but it is fairly steady and continuous subsequently. In the case of J. S., the subject of this special study, as previously stated, there was a loss of but 17 pounds in sixty-two days before dinitrophenol was given. Under a strictly controlled diet, three partial fasting days being included in a total of seventeen days up to the day of his discharge from the hospital on October 12, his weight fell to 187 pounds, a further loss of 10 pounds, or at the rate of three-fifths of a pound per day. The metabolic study in the case of J. S. shows the time factor in the development and the extent to which the basal metabolism rate is raised on a dose of but 5 mg. per kilo. At the same time the respiratory quotient was slightly lowered on September 25. With but one meal on this day and no breakfast next morning, a further lowering of the respiratory quotient is what would be expected. This progressive drop in the respiratory quotient, during the first two days of the study, does not necessarily mean that the oxidation of fat is stimulated, though very suggestive. The low calory intake must also be considered. It seems equally evident that the extra oxidation caused by the drug was not accomplished at the expense of protein or carbohydrate. The progressive increase in calories of fat burned per hour on each of the first two days, when considered in the light of the other findings portrayed, makes it very probable that the very evident increase in oxidation is at the expense of the fat. A side light is shed on this feature in our obese cases of cardiac decompensation. Presumably the interface phenomena of fat and water in the edematous cardiac case, in some way affords a firmer binding of the two. The basal metabolic rate does not mount quite so high, and until the tissue fluids have been mobilized and in large part excreted, there is no appreciable loss of flesh and the loss is very gradual when it does occur. An attempt to reduce the weight of the obese individual with myocardial involvement is manifestly justifiable, but it remains in doubt as to whether it is advisable to attempt it by means of dinitrophenol.

The study of sugar tolerance after 100 gm. of glucose plus 5 mg. per kilo of the drug, indicates that sugar utilization during the first hour may be inhibited. At the end of the second hour the blood sugar is essentially normal,

and the respiratory quotient of 0.93 is what one would anticipate, even had no drug been given. In experimental work on animals with dinitro-alpha-naphthol, an early rise in the blood sugar has been noted and the liver and muscle glycogen are reduced.

It is of further interest to note that a single dose of 5 mg. per kilo, given during the fasting state, caused a rise in the rate of 31 per cent in less than two and one-half hours, and a total rise of 38 per cent in about six and one-half hours. Twenty-four hours after the administration of the drug, the rate remained 18 per cent above his basal rate of the previous day. On another occasion, two hours after a dose one mg. less per kilo, given with his regular breakfast, there was a rise of 45 per cent in his rate, but this was regarded as a summation effect. The rapid action of the drug upon heat production in the fasting state was very similar on the two days. On the first day this was 31 per cent and on the second day 28 per cent, each in a little over two hours. Oxidation was much less rapid and less pronounced when the drug was given with a glucose meal, than when it was given alone and in the fasting state.

#### COMMENT

1. A metabolic study of the effects of dinitrophenol has been reported.
2. The rapid increase and degree of oxidation have been shown, (a) in the fasting condition, (b) when given with a glucose meal, (c) the summation effect of drug and regular meal.
3. The probability that oxidation occurs at the expense of fats has been suggested.
4. The question of dosage has been considered and in the light of present knowledge, doses of 2 to 3 mg. per kilo at one dose daily have been advised.
5. It would seem unwise to use it in a case of diabetes or in an edematous individual.
6. In appropriate doses, though its oxidative properties are striking, weight loss is not rapid, nor is there any appreciable effect upon temperature, pulse, or respiration.

## ABSORPTION OF DEXTROSE FROM THE HUMAN GASTROINTESTINAL TRACT\*

MAX WISHNOFSKY, M.D., BROOKLYN, N. Y.

IN 1925, Cori,<sup>1</sup> as a result of an ingenious method by which absorption of saccharides from the entire gastrointestinal tract of rats was studied, came to the conclusion that (1) a proportionality exists between the absorbing surface of intestine and body weight in growing male and female rats, and (2) the rate of absorption of hexoses is constant and is independent of the absolute amount and of the concentration of sugar present in the intestine. He calculated the absorption rate to be 1.78 grams of dextrose per kilogram of rat.

Trimble, Carey and Maddock,<sup>2</sup> utilizing Cori's technic in dogs, made substantially the same observations. They found that the rate of absorption of dextrose from the intestinal tract of dogs is one gram per kilogram of body weight per hour; also, that this rate is constant and not influenced by: (a) the concentrations; (b) the absolute weight of dextrose ingested; (c) lengths of absorption period; (d) weights of the animals used; and, (e) excitement occasioned by experimentation.

MacKay and Bergman,<sup>3</sup> also employing Cori's method of study, made findings entirely at variance with those of the latter. They concluded that (1) the absorption rate of dextrose per unit of time from the intestinal tract of male and female rats of various ages bears a more constant relation to body surface than to body weight, and (2) the absorption coefficient (amount of dextrose absorbed per unit of body surface per hour) is raised by increases in either the amount or concentration of dextrose administered. Whatever the dose, the rate of absorption decreases with time after it is given. Pierce, Osgood and Polansky<sup>4</sup> and Burget, Moore and Lloyd<sup>5</sup> previously had made observations which are in agreement with those of MacKay and Bergman. In addition they found that the total amount of dextrose absorbed and the amount absorbed per 100 gram of body weight per hour varies within wide limits. These variations are not dependent on body weight or upon the actual amount of dextrose fed.

In animal experiments, then, the findings and conclusions of the various investigations are diametrically opposed to each other.

Jacobsen<sup>6</sup> found that the administration of water does not influence the "fasting" blood sugar level. Strouse<sup>7</sup> made similar observations, and in

\*From the Diabetic Clinic and the Departments of Pathology and Metabolism of the Jewish Hospital of Brooklyn.

Received for publication, November 28, 1933.

Aided by a grant from the Committee on Scientific Research of the American Medical Association.

addition noted that the "fasting" blood sugar level is not changed by increased excretion of water. Boe<sup>3</sup> found in dogs that the administration of a dilute solution of dextrose causes only an insignificant rise in blood sugar; whereas a more concentrated solution caused a much higher rise. This may be taken as evidence that the more concentrated the solution the greater is the rate of absorption.

Direct methods of study of the absorption of dextrose from the gastrointestinal tract are, of course, not applicable to man. We are, as a consequence, deplorably ignorant of this subject as far as human beings are concerned. From a study of the respiratory quotient curve after the administration of dextrose, Johansson<sup>9</sup> concluded that the maximum rate of absorption of dextrose in man is between 80 and 100 gm. per hour.

In this paper will be reported the results of an investigation, by an indirect method, of the laws governing the absorption of dextrose from the human gastrointestinal tract.

In a normal individual it is practically impossible to raise the blood sugar level above 180 mg. per 100 c.c. of venous blood on the administration of dextrose by mouth, for the amount of insulin secreted is easily capable of causing the abstraction of dextrose from the circulation regardless of the rapidity with which it is absorbed from the intestine. In diabetes mellitus, however, hypoinsulinism exists and the amount of insulin secreted at any particular time is fixed and dependent on the severity of the case. The amount of dextrose that the individual diabetic can metabolize per unit time follows the equation determined by Allan.<sup>8, 10</sup> If the absorption of a certain amount of dextrose per unit time in a given diabetic gives rise to a certain blood sugar curve, the absorption of a greater amount will cause a higher blood sugar curve because the amount of insulin secreted remains constant. In the same diabetic, the greater the amount of dextrose absorbed in a given time, the higher will the blood sugar curve be. If, then, one gives to the same diabetic varying amounts of dextrose, two days apart, the blood sugar curves will be equal in height or higher with the larger dose, depending on whether the rate of absorption is the same or greater with the larger dose.†

#### METHOD OF PROCEDURE

With this a basis, experiments were performed on 14 female diabetics. To each one two doses of dextrose were given; a large one on one day, and a smaller one two days later. To a group of three, 125 gm. of dextrose were given on the first day and 25 gm. two days later; to a second group of six,

\*The dextrose equivalent of insulin in any given case is not a constant, but is represented by the equation  $g(u)^{0.33} = 10^{1.66}$  where  $g$  is the amount of dextrose metabolized by each unit, and  $u$  is the number of units of insulin given. The dextrose equivalent of insulin is increased if the amount of insulin remains constant and the amount of dextrose increased, or if the amount of dextrose remains constant and the amount of insulin decreased; the dextrose equivalent is decreased if the amount of insulin is increased and the amount of dextrose remains constant, or if the amount of dextrose is decreased and the amount of insulin remains constant. In this situation the amount of insulin remains constant. If more dextrose is absorbed the dextrose equivalent will be increased, so that the rate of rise of the blood sugar curve will be less and less with increasing rate of absorption of dextrose.

†It is realized that the blood sugar level is influenced by the secretions of the thyroid, adrenal and pituitary glands, and other factors. It is fair to assume that these factors, like insulin, remain constants during the period of experimentation.

either 100 or 150 gm. were given on the first day and 50 gm. two days later; to a third group of five, 150 gm. were given on the first day and 75 gm. two days later. The anhydrous dextrose was dissolved in distilled water and made up to 500 c.c. An hour after the administration of the dextrose 250 c.c. of water were given. The total volume was therefore 750 c.c. in each case for both the large and the small dose.

The dextrose was given in the morning after a fast of fourteen hours. Blood (venous) specimens were taken at the "fasting level," immediately before ingestion, and forty-five minutes, two hours, and in some cases, three hours after the ingestion of the dextrose. The sugar content of the blood was determined by the macro Folin-Wu method. The urine was collected at the end of the first, second, and in some of the cases, third hour after ingestion of the dextrose, and its sugar content determined by Benedict's method.

#### ANALYSIS OF RESULTS

The results are incorporated in Table I. After careful consideration it was decided that the best method of determining the influence of the different doses on the blood sugar curve was to calculate the differences in rise of blood sugar concentration when the large dose and the small one were given, from the "fasting level" to the "forty-five-minute," "two-hour," and "three-hour" levels, respectively. To illustrate: in Case 1 (Table I) the "fasting level" when 125 gm. of dextrose were given was 214, and the "forty-five-minute level," 332, indicating a rise in blood sugar concentration of 118 mg. per 100 c.c. of blood. When 25 gm. of dextrose were given the "fasting level" was 230 and the "forty-five-minute level," 332, indicating a rise in blood sugar concentration of 102 mg. per 100 c.c. of blood. The difference in elevations is 16. A plus sign is arbitrarily placed in front of the 16 to indicate that the rise is greater when the larger dose is given. A minus sign, on the other hand, indicates that the rise is greater when the smaller dose is given.

Analyzing the blood sugar concentrations at the "two-hour level" it will be observed that in Group I, in all cases, the rise is markedly greater with the larger dose. This also holds true for all the cases in Group II, although the difference is much less and in one case (Case 9) is within the limit of error of the method used to analyze the blood. In Group III, however, a striking change has taken place. Here, in four out of five cases, the rise is greater when the smaller dose is given. This is of fundamental significance for it indicates that at the end of two hours at least as much dextrose is being absorbed when 75 gm. are given as when 150 gm. are given; in other words, *the rate of absorption of dextrose is the same regardless of the absolute amount in the intestine.* As a corollary to this it may be stated that *the rate of absorption is constant.*

An interpretation may now be given for the greater rise in blood sugar concentration at the "two-hour level" in Groups I and II when the larger dose is given. The reason is that the dextrose, when the smaller dose is given, has been completely absorbed before the end of two hours so that the blood sugar concentration has been dropping for some time before the "two-hour

level" is reached. This is brought out in Group II at the "three-hour level." Here in every one of the four cases studied, the difference in rise is decidedly greater than at the "two-hour level." Also, in Group I, the difference in rise at the "two-hour level" is much greater than in Group II because the blood sugar concentration in the former has been dropping for a much longer time.

It follows, then, that when 75 gm. of dextrose are given (Group III), the amount remaining in the gastrointestinal tract at the end of two hours is less than 25 gm.; whereas when 150 gm. are given, the amount remaining at the end of two hours is between 75 and 100 gm. The important deduction from these findings is *that the amount of dextrose absorbed in two hours from the gastrointestinal tract of the average adult diabetic lies somewhere between 50 and 75 gm.* Since there is no reason to suppose that the rate of absorption differs in normals from diabetics, this statements holds for all adults.

Analyzing the "forty-five-minute level" one finds that in 13 out of the 14 cases the rise is greater with the larger dose. In 6 out of the 14 cases the figure for the difference in rise is within the limit of error of the method used for analyzing the blood. In spite of this, one is impressed that the difference in rise is somewhat greater when the larger dose is given. It is no greater in the group receiving 25 gm. than in the one receiving 75 gm. What is the cause for this greater rise with the larger dose at the "forty-five-minute level"?

It was stated above that some investigators<sup>3, 4, 5</sup> found that the rate of absorption is increased by increase in concentration of dextrose administered; also, that Boe<sup>8</sup> observed that the level of the blood sugar curve is higher when a more concentrated solution is given. In the experiments recorded in Table I, the volume was kept constant; the concentration necessarily varied.

The question then is: Is the greater rise with the larger dose due to the fact that the solution administered was more concentrated? To determine this point, the following experiment was performed. To seven patients, suffering from diabetes mellitus, varying doses of dextrose, of equal concentration, namely 32 per cent, were given two days apart. On one day 125 gm. and two days later 45 gm. of dextrose were administered. Venous blood was taken at the "fasting level" immediately before ingestion, and forty-five minutes after ingestion. The results are incorporated in Table II. It is to be observed that in 6 out of 7 cases the rise is greater with the larger dose, and that the differences in rise are of the same magnitude as in Table I. The conclusion to be drawn is that the height of the blood sugar curve is not influenced by differences in concentration of the dextrose administered. As a corollary it may be stated that the rate of absorption of dextrose is not influenced by this factor. I am at a loss to explain the greater rise in blood sugar concentration with the larger dose at the "forty-five-minute level."

The observations made above have a practical value. The dextrose tolerance test, especially when combined with a simultaneous study of the respiratory quotient curve,<sup>11</sup> constitutes the best method of determining the presence of diabetes mellitus and also its severity.<sup>12</sup> In a symposium on the

dextrose tolerance test, Gray<sup>13</sup> lists the test substances and doses used by various investigators in the study of carbohydrate metabolism. They are as follows: from 20 to 25 gm. of dextrose; 50 gm. of dextrose; 70 gm. of dextrose; 100 gm. of dextrose; from 150 to 200 gm. of dextrose; 100 gm. of levulose; from 50 to 100 gm. of cane sugar; 25 gm. of starch; 50 gm. of starch; from 70 to 100 gm. of starch; and a mixed meal. In addition it may be mentioned that Janney and Isaacson<sup>14</sup> use 1.75 gm. of dextrose per kilogram of body weight. The choice of these doses and substances in all instances is purely arbitrary.

John<sup>15</sup> performed dextrose tolerance tests on 50 patients with diabetes, using 100 gm. of dextrose as a test dose. He found that in 86 per cent of the cases the maximum rise occurs within two hours after the ingestion of the dextrose. This also holds true when 150 gm. of dextrose are given, for in 5 cases in which this dose was given by me (see Table I) all had the maximum rise within the first two hours. The character of the curve *after*

\*In milligrams per 100 c.c. of blood.

the first two hours is determined by the size of the dose; the larger the dose, the longer it will take for the "fasting level" to be attained. In performing a dextrose tolerance test it is of value not only to determine whether the blood sugar curve is or is not higher than normal but also the maximum rise obtainable. From Table I it can be seen that 75 gm. of dextrose is the smallest dose that will give a maximum rise in blood sugar in the average adult diabetic.

It is also important to note that a dose of 50 gm. of dextrose or less may fail to disclose a potential or very mild diabetic if the "fasting level" is normal. The reason is that because of the complete absorption of the dextrose before the end of two hours post cibum, the blood sugar may drop to the "fasting level" at the end of the two hours. This event would not occur if 75 gm. of dextrose are given. Seventy-five grams of dextrose is the minimum dose that can be used to detect diabetes mellitus. It is accordingly proposed that 75 gm. of dextrose be used as the test dose.

A point which is not entirely relevant to the subject of this paper may, however, with value be discussed here. Does the administration of large quantities of dextrose, such as the patients received in these experiments, lead to a breaking down of tolerance? Joslin<sup>16</sup> strongly deprecates the use of the dextrose tolerance tests in diabetics, although he has never seen one injured by them. Ohler<sup>17</sup> also argues that on theoretical grounds the giving of large quantities of dextrose is harmful. Allen,<sup>18</sup> in his work on partially depancreatized dogs, found that excessive feeding of carbohydrates, especially where given in a rapidly absorptive form, such as dextrose, leads to a rapid breaking down of tolerance. Several years ago I<sup>12</sup> observed for several months seven diabetics who had had two dextrose tolerance tests performed two days apart. The test dose was 100 gm. of dextrose. None showed the slightest change in tolerance as a result of this procedure. Nor was there any depreciation of tolerance in any of ten patients of Table I as a result of receiving

\*In milligrams per 100 c.c. of blood.

the large quantities of dextrose. It may be stated categorically that the giving of large quantities of dextrose does not cause the slightest depreciation of carbohydrate tolerance in diabetics.

#### SUMMARY AND CONCLUSIONS

The absorption of dextrose from the gastrointestinal tract has been studied quite intensively in animals. The results and conclusions of the various investigators are conflicting.

This subject has been almost completely neglected in man.

An indirect method of studying this subject in human beings is described. It consists in performing repeated dextrose tolerance tests on diabetics, using varying doses of dextrose. The rationale for this procedure is outlined.

The conclusions drawn from the data obtained are as follows:

1. The rate of absorption of dextrose from the human gastrointestinal tract is the same regardless of the absolute amount present. A corollary to this is that the rate of absorption of dextrose is constant.
2. The amount of dextrose absorbed from the gastrointestinal tract of the average adult in two hours lies somewhere between 50 and 75 gm.
3. The rate of absorption from the gastrointestinal tract is not influenced by the concentration of the solution of dextrose administered.
4. Seventy-five grams of dextrose is proposed as a standard dose to be used in performing a dextrose tolerance test.
5. The ingestion of large quantities of dextrose by patients with diabetes does not cause the slightest depreciation of their tolerance for carbohydrates.

NOTE: I wish to express my thanks to Miss Louise Zelenko for technical assistance.

## HISTOCHEMICAL STUDIES OF ORGANS OF TUMOR-BEARING RATS BY THE MICROINCINERATION METHOD<sup>2</sup>

W. C. HUEPER, M.D., PHILADELPHIA, PA.

THE study of the amount, character and distribution of mineral matter in normal and malignant tissues has been recently advanced by the introduction of the microincineration method (Policard,<sup>1</sup> Schultz-Brauns,<sup>2</sup> Scott and Horning<sup>3</sup> and others). The value of the observations made, especially those of comparative character, is, however, impaired by the fact, that the great majority of the investigators used paraffin sections in their work.

Fixation and dehydration of tissues cause not inconsiderable changes in the amount and distribution of the mineral substances in the cells (Schultz-Brauns,<sup>2</sup> Policard and Okkels,<sup>4</sup> Tschopp,<sup>5</sup> Cowdry<sup>6</sup>). The degree and type of changes produced by fixating and dehydrating agents depend upon their chemical nature, a time factor and possibly also on the physicochemical constitution of the tissues.

Many of these defects in the proper preparation of sections for microincineration have been eliminated in the technic of frozen sectioning developed by Schultz-Brauns,<sup>2</sup> who modified the commonly used method by cutting unfixed tissue with a knife cooled with carbon dioxide to  $-15^{\circ}$  to  $20^{\circ}$  C. Losses of mineral substances are thereby completely avoided and the possibility of artificial displacements of the cellular mineral skeleton is markedly decreased.

The present communication represents a report of the results of an investigation on the mineral skeleton of malignant cells studied in frozen sections of fresh, unfixed tissue cut according to a modification of the method of Schultz-Brauns (Hueper<sup>7</sup>). In the second part of the paper observations are recorded which were made on normal and neoplastic tissues of rats treated with parathormone and viosterol.

### PART I. MINERAL STRUCTURE OF MALIGNANT TISSUE

The tumor tissue used was obtained from rats which had been inoculated with a transplantable sarcoma, Philadelphia No. 1 and a transplantable medullary carcinoma, Walker No. 256 respectively, a detailed histologic description of which has been published in a previous paper (Waldschmidt-Leitz, McDonald, Hueper and Coworkers<sup>8</sup>). Sections were prepared with the cooled

\*Received for publication, December 6, 1933.

knife technic from fresh, unfixed tumor tissue removed from the peripheral parts of the tumors. Alternating sections were stained and incinerated respectively. For the incineration an electrically heated quartz furnace was used, the maximum temperature of which was adjusted to 600° C. The sections were kept in the oven for about forty-five minutes. They were left in the incinerator until they were cool and were then covered with a glass coverslip which was sealed with paraffin. A Zeiss cardioid condenser was used for the dark-field examination. A small Leitz camera which had no bellows and which could be attached to the eyepiece was used in the photographic work. The sections to be stained were first put into 95 per cent alcohol and then stained in the ordinary way with hematoxylin-eosin or hematoxylin-phloxin.

The stained sections show more or less densely packed tumor cells, embedded in a loose connective tissue stroma. The nuclei are relatively large and contain dark stained chromatin material arranged in irregular lobules and threads. A complete or incomplete ringlike accumulation of the chromatin in the periphery of the nuclei is exceptional. The cytoplasm is moderate to scanty in amount and is indistinctly outlined in the sarcomatous tumor, while rather well defined in the carcinomatous neoplasm. Small localized foci of degeneration and necrosis are scattered in moderate number in the tissue. In these degenerative areas pyknotic nuclei are numerous. Pseudopapillary-cystic formations are seen in some of the regressive foci. The necrotic areas are pink in color and contain chromatic nuclear fragments. Diffuse, usually perivascular hemorrhages are occasionally observed.

The ash pictures of the tumor sections vary considerably in different portions of the same section. In the areas corresponding to the above described healthy parts of the tumor a scanty bluish to bluish gray reflecting matrix of very small granules is present. Embedded in it numerous, smaller and larger, somewhat ill-defined, irregularly round shaped rings are seen. They are either exclusively or mainly composed of accumulations of fine, bluish reflecting particles. The center of these rings is sometimes empty, usually, however, filled by a small clump of the same bluish reflecting substance or of a mixture of the bluish and a coarse white reflecting matter. Small white reflecting particles occur also in some of the bluish rings. Reddish or brownish red reflecting granules are usually absent in the ring formations. They appear in only a few of the sections, where they participate in appreciable amounts in the composition of the rings and their central content in some areas. Surrounding the individual rings an indistinctly outlined area of less densely packed bluish granules fades away into the above described matrix.

The rings are much more distinct in those areas which show in the stained sections evidence of cell degeneration. They stand out as more or less solid, white reflecting formations, consisting either of a continuous or a discontinued, bead-like accumulation of coarse, white particles. The central portions of the rings are sometimes empty, but in general they are filled with the same white reflecting material of which the rings are composed. Solid

white, round bodies are often seen in such areas in place of ring formations and are apparently the result of a merger of the ring and its central content. White granules are also found in varying number in the zone surrounding the individual rings. There is not infrequently a second, outer ring present, consisting of white particles arranged in a bead-like formation which seems to demarcate the cell from the intercellular matrix. A larger amount of mineral matter, in which the white reflecting particles are prominent, is also found in the matrix.

The necrotic foci of the tumor tissue are characterized in the incinerated section by an incomplete or complete loss of the cellular structure. There are more or less dense, diffuse accumulations of white reflecting matter, which contains sometimes smaller and larger reddish brown particles.

As the interpretation and significance of the observations recorded depends to a certain extent upon the chemical nature of the various elements visible in the ash pictures, brief reference may be made to the information available at the present time on this subject. It is conceded by all investigators that the white reflecting particles represent calcium, probably in the form of calcium oxide. The brownish red to red granules seen in the ash are iron oxide. The nature of the bluish reflecting material is not definitely known. Policard suggested that it represents potassium and sodium. Scheid<sup>9</sup> has called attention to the presence of brownish, homogeneous, glassy or granular substances, which appear especially often in tissues containing large amounts of phosphatids, such as the white substance of the brain. These droplets, which may occasionally express a similarly colored liquid forming a network in the ash (artefact), are according to the investigations of Tschopp<sup>5</sup> and Scheid<sup>9</sup> phosphorus oxide. It may be mentioned in this connection that identical formations of droplet or network type have been observed in the incinerated sections of the two tumors examined and were found in general in close relation to degenerative and necrotic foci, where, however, also brownish red granules of iron character were frequently met.

#### COMMENT

The examination of the incinerated sections of the two transplantable rat cancers showed that the inorganic remains of the healthy tumor tissue are mainly bluish reflecting granules, which represent according to Policard's opinion sodium and potassium. Similar observations on the color of the ash of malignant and normal proliferating tissue were made by Olch<sup>10</sup> who reported that the ash of human breast and skin carcinomas and of the epithelial proliferations in chronic cystic mastitis, in hyperkeratoses and warts has a bluish color. Calcium appears either to be absent or to be present only in small amounts in the mineral skeleton of the healthy tumor cell. Iron does not seem to play any important rôle in the mineral constitution of the cytoplasm and the nucleus of the cells of the two tumors examined.

While the ring-like accumulations of mineral matter are located in the region where the nucleus is found in the stained sections, it appears to be doubtful, judging from the size and diameter of some of the rings, whether

these formations are located in the peripheral parts of the nucleus or are mineral matter absorbed to the nuclear surface or represent to a certain extent accumulations of minerals in the perinuclear space. These mineral rings can, however, not be looked upon as artefacts resulting from the action of fixating and dehydrating agents upon the cells, as suggested by some investigators.

These findings do not substantiate in some respects those recently made by Scott<sup>3</sup> and Scott and Horning,<sup>3</sup> who reported that malignant cells are characterized by an extraordinary concentration of iron and to some extent also of calcium in the peripheral margins of the nuclei resembling in this regard the mineral structure of embryonic cells. An explanation for this discrepancy cannot be offered at the present time. The only conclusion which can be justly drawn from the evidence at hand seems to be, that not all malignant cells resemble in their mineral structure that present in embryonic cells.

The observations made do not confirm another claim of Scott in regard to the presence of correlations existing between the mineral structure of the nucleus of malignant cells, the distribution of chromatin substance and the absorption picture obtained by ultraviolet ray photography. Scott has to a certain extent disproved his own contention in his experiments with opalinids, where he noted the absence of a relation between the scanty amount of nuclear ash and the good amount of chromatin present. The chromatin substance of nuclei of malignant cells in tumors in men, mice or rats is moreover not accumulated in the peripheral parts of the nuclei as contended by Scott. An accumulation of chromatin matter in this region is in general considered as evidence of cell degeneration. The location of the mineral substance as demonstrated by the incineration method does, therefore, not correspond to that of the chromatin matter of healthy tumor cells. The actual existence of the correlations cited above seems to be insufficiently supported by reliable experimental evidence.

In regard to the absolute amount of mineral matter in malignant cells, the investigations reported above do not support the conception that malignant cells have a higher mineral content than normal cells (Scott). This impression is gained by a comparison of ash pictures of areas of healthy tumor tissue with those of organs of similar cellularity, such as liver, spleen, pancreas, kidney, lymph node, salivary gland, etc. Much apparently depends upon the relative size of the cells and their functional state. Oleh<sup>10</sup> reported that the cells of the resting mammary gland contain large amounts of calcium. Policard and Pillet<sup>11</sup> stated that proliferating tissue has a low ash content and Policard and Doubrow<sup>12</sup> noted that the ash content decreases with the increase in the embryonicity of the tumor. Schultz-Brauns mentioned during a brief discussion of the ash content of various tissues that benign as well as malignant neoplasms show in general a light to moderate amount of ash. He added, however, that marked variations may occur among the ash content of individual tumors.

Considerable differences in the density of the mineral ash exist also between different parts of the same tumor. These have been referred to variations in the vital status of the cells. The ash and especially its calcium com-

Fig. 1.—Incinerated healthy sarcomatous tissue showing rather faintly visible rings of bluish reflecting granules scantily mixed with white particles.

Fig. 2.—Ashed section of degenerating sarcomatous tissue with prominent white rings.

Fig. 3.—Degenerating sarcomatous tissue with white rings and central "calcifications."

Fig. 4.—Very edematous degenerating sarcomatous tissue with marked central "calcifications" and distinct white outer rings, demarcating the cellular outline.

Fig. 5.—Advanced degeneration of sarcomatous tissue with partial loss of cellular structure in the ashed section.

Fig. 6.—Necrotic focus in sarcomatous tissue characterized by dense accumulation of calcium particles.

ponent increases in direct proportion to the degenerative state of the cells and is apparently most abundant in areas of complete necrosis.

Shear<sup>11</sup> stated in his recent review on the rôle of different minerals (sodium, potassium, magnesium and calcium) in cancer, that it is the current view that the calcium content of tumors increases with increasing age and with increasing extent of necrosis. Policard and Doubrow<sup>12</sup> noted that degenerating and necrotic tumor tissue contains more ash than living tissue. Scott and Horning<sup>3</sup> remarked that their investigations furnished supplementary evidence for this observation. The experimental data obtained in this study confirm this conception and supply at the same time additional information in regard to the intracellular mineral changes and shifts which are associated with the process of degeneration.

An increase in the amount of calcium particles in the nuclear mineral ring represents apparently the first sign of a decreasing vitality and beginning degeneration of the cell. Following this nuclear calcinosis calcium particles are accumulated in increasing amounts in the central portions of the ring, until ultimately a union between the ash of the ring and of the central nuclear mineral deposits occurs. Accompanying this nuclear change there is also an increase in the number of calcium particles in the cytoplasmic region combined with a deposition of larger calcium granules in the peripheral parts of the cell (membrane?), where thereby a second outer ring is formed. With the ultimate complete disintegration of the cellular structure with progressing necrosis a definite mineral skeleton of the cells disappears and diffuse accumulations of mineral matter mainly representing calcium take their place. Older necroses are characterized by denser, almost solid masses of coarse calcium particles.

It was noted that necroses which showed in the incinerated sections marked deposition of calcium were not stained blue with the hematoxylin stain, but were pink, indicating thereby that the calcium present in these necroses is either too small in amount to be visible in the stained section or that it is present in a form which cannot combine with the hematoxylin. If the last conception should be correct the stainability of intracellular calcium would depend upon the physicochemical state in which this substance is held. A certain similarity would exist in this respect to the stainability of intracellular fat. As cellular degeneration is often accompanied by an accumulation of fat, correlations may exist between the increase of mineral ash, especially calcium, and that of fat in the degenerating cell (Schultz-Brauns). It is, however, doubtful, if an accumulation of calcium in the cell designates always a degenerative process or if it may also characterize a cell with low vital activities.

#### PART II. THE EFFECT OF PARATHORMONE AND VIOSTEROL MEDICATION UPON THE MINERAL CONTENT OF NORMAL AND MALIGNANT TISSUES IN RATS

Various authors have attempted to influence cancer growth by the introduction of substances which affect the calcium metabolism, such as calcium salts, Irradiated ergosterol and parathyroid hormone, into the cancerous organism

(Goldfeder,<sup>14</sup> Paik,<sup>15</sup> Barelli,<sup>16</sup> Sugiura and Benedict,<sup>17</sup> Goerner,<sup>18</sup> Goerner and Shafroff,<sup>20</sup> Sumi,<sup>19</sup> Bischoff and Maxwell,<sup>21</sup> Reding and Slosse<sup>22</sup>). Shear<sup>13</sup> came, in his recent review on this subject, to the conclusion that parathormone treatment is ineffective as an agent which may inhibit or stimulate malignant growth and that vitamin D is without any reliable antigrowth action. This conception is confirmed by observations made by me some time ago on a larger series of cancer patients who received calcium salts, viosterol and parathormone over a prolonged period and in relatively large doses.

In view of the controversial observations made on the blastic action of vitamin D and parathormone, a histochemical study of ashed sections prepared from cancer tissue of animals, treated with these two agents, seemed to be of interest, as it could be assumed that any action of these substances on the tumor would very likely be associated with definite changes in the mineral constitution of the cells.

Six rats, three inoculated with the transplantable sarcoma, Philadelphia No. 1, and three inoculated with the transplantable carcinoma, Walker No. 256, were used in the parathormone experiment. After the tumors had reached the approximate size of a walnut and after a small piece of the tumors had been removed for comparative study, the rats received subcutaneous injections of parathormone. One animal was killed twenty-four hours after the injection of 50 units of parathormone; three rats were killed sixteen hours after the injection of 100 units of parathormone. Rat 5 was sacrificed sixteen hours after injection of 150 units and Rat 6 received a total of 250 units in the course of three days and died on the fifth day after the beginning of the medication.

As the rat is rather resistant to parathormone (Collip,<sup>23</sup> Tweedy and Chandler,<sup>24</sup> McJunkin, Tweedy and Breuhaus<sup>25</sup>), relatively large doses of parathormone are required for the production of toxic degenerative organic lesions, such as those rather readily obtained in dogs (Hueper).

In the viosterol experiment six rats with sarcoma, Philadelphia No. 1, were fed with 0.75 c.c. of viosterol 10,000 X daily by mouth with a dropper. After five days of this medication the rats became listless and showed a coarse fur. The treatment was discontinued and one animal was killed four days later. After an interval of a week the medication was resumed for a period of four days. One animal died two days after the resumption of the feeding and one was killed at that time. The remaining three animals were killed ten days later, while they were still showing symptoms of viosterol intoxication.

Any inhibitory effect of the viosterol medication upon the growth rate of the tumors was not observed. This may be noteworthy, in spite of the small number of animals used, on account of the rapid growth of these neoplasms.

The autoptic examination of the rats did not show any macroscopic pathology in the tumors and organs which might have been referred to the medication given, with exception of Rats 5 and 6, where irregular whitish, soft areas and streaks were found on the cut surface of the kidney and heart, indicating the presence of necroses.

The histologic findings in the organs of the rats in both groups were essentially identical. The following organs were examined: tumor, salivary gland, heart, lung, liver, pancreas, spleen, kidney, lymph node, suprarenal gland, and skeleton muscle.

The stained and incinerated sections prepared from the tumors of the

Fig. 7.—Vascular and myocardial calcification in the heart after parathormone poisoning.

Fig. 8.—Accumulation of calcium particles in the myocardium without evidence of degenerative changes in the stained section.

Fig. 9.—Accumulation of calcium in the muscularis of the esophagus of Rat 6, which died from parathormone poisoning.

Fig. 10.—Calcifications in the kidney of Rat 6.

treated animals did not reveal any appreciable and fundamental difference from those made before the medication was started. There were no changes in the stainability of the cytoplasm and of the nucleus of the tumor cells. The ashed sections were essentially identical with those previously described.

There was neither an increase nor a decrease of mineral matter, especially of calcium, in the tumor cells and the intercellular spaces.

In contrast to these negative results in the tumors definite histologic and histochemical pathology was found in some of the organs of the treated rats, especially in Rats 5 and 6, indicating that the medication given had been intense enough to cause pathologic lesions in some parts of the organism.

*Heart*.—There is a moderate to marked interstitial and especially perivascular leucocytic infiltration of the myocardium. A bluish stained hyaline material is found here and there in the perivascular spaces in between the leucocytic exudate. The walls of the myocardial vessels of Rats 5 and 6 are markedly thickened and deeply blue stained. Reddish and blue stained necroses surround and extend from these vessels into the myocardium. The incinerated sections show a moderate, spotty increase of white reflecting particles. The leucocytic infiltrations appear as small accumulations of strongly reflecting white dots. The vascular walls in the heart of Rats 5 and 6 appear as thick, solid white rings, from which less massive accumulations of white matter extends into the surrounding ash which is also rich in white reflecting granules.

*Esophagus*.—The muscularis of the esophagus of Rat 6 is dark grayish blue in color and contains dense accumulations of calcium particles in the ashed section.

*Liver*.—In some of the livers examined the cytoplasm of the Kupffer cells and of scattered individual liver cells is blue stained. The distribution of accumulations of white granules corresponds approximately with that of these bluish stained cells. There is a general increase of white ash. It is noted that the liver cell areas surrounding the central veins do not participate in this increase, but are composed of bluish and reddish reflecting ash.

*Kidney*.—The tubular epithelium of the cortex shows a distinctly bluish stained substance located in the pink stained cytoplasm. This bluish material surrounds sometimes the nucleus and exudes and fills the lumina of the tubules. Small, isolated foci of necroses are occasionally seen. In the kidneys of Rats 5 and 6 extensive necroses of the tubular epithelium are present. There are also localized calcifications of the necroses and calcium casts in the tubules in great number. The walls of many of the smaller vessels are thickened and intensely blue stained, indicating a high degree of calcification.

The ashed sections show a marked increase of white reflecting material, which often forms dense clumps or rings corresponding in their distribution with that of the tubular necroses and vascular calcifications, respectively, seen in the stained sections.

The microscopic examination of the stained and ashed sections of the other organs mentioned above did not reveal any differences from the conditions seen in the sections of a series of three normal rats of the same strain and approximate age as the experimental animals.

#### COMMENT

The observations made seem to indicate that the cells of the two rat tumors used do not belong to that group of tissues in which disturbances of the mineral metabolism caused by overdosage of parathormone and viosterol, respectively, result in local degenerations and necroses. The absence of any appreciable changes in the amount, character, and distribution of the mineral matter of the cancer cells following the medication of parathormone and viosterol suggests that the malignant tissue is apparently unable to withdraw calcium from the hypercalcemic blood, because the calcium is present in the blood in a form which cannot be taken up by the malignant cells. This explanation is supported by the observations of Kluge<sup>27</sup> who found, that there is a marked difference in the absorption of calcium compounds by tumor tissue

depending on their organic or inorganic character. While the subcutaneous injection of inorganic calcium compounds resulted in a marked temporary increase of the calcium content of the tumor tissue, its calcium content was barely increased when organic compounds were used.

The presence of a bluish stained substance in the perivascular spaces of the myocardial vessels and in the cytoplasm of the renal epithelium and liver cells together with the corresponding increase of calcium particles in these cells according to the observations made in the ashed sections suggests, that intracellular disturbances of the mineral metabolism precede and cause the degeneration and necroses of the myocardium and kidney occurring in parathormone and viosterol poisoning. This conception receives additional support by previous investigations of Hueper,<sup>7</sup> McJunkin, Tweedy and Breunhaus<sup>25</sup> and Ham.<sup>26</sup> It is obvious that the lethal cellular calcinosis may not always be followed and intensified by an additional necrotic calcification. The presence of a hypercalcemia will, however, favor this process. The contrast existing between the marked increase of calcium in degenerative and necrotic foci, according to the ashed sections, and the absence of a positive staining reaction for calcium in these areas, according to the stained sections, seems to suggest the possibility that the demonstration of calcium in the tissue with the hematoxylin stain depends not only on the amount but also on the character of the calcium compound present.

#### CONCLUSIONS

1. Microincineration of two transplantable rat cancers showed that the healthy tumor cells consisted almost exclusively of bluish reflecting granules, representing presumably sodium and potassium.

2. Iron and calcium did not seem to play any important rôle in the mineral constitution of these cells.

3. Cellular degeneration in these two tumors was characterized by an increase of the calcium content of the cells, manifested mainly in the formation of white nuclear rings.

4. The character and composition of the mineral skeleton of the tumor cells could not be changed by the medication of parathormone and viosterol.

5. Degenerations and necroses in the kidney and heart of rats receiving excessive amounts of parathormone and viosterol were apparently caused by the toxic action of an intracellular calcium accumulation.

I am indebted for technical assistance to Miss M. Russell, Cancer Research Laboratories, University of Pennsylvania.

# THE SIGNIFICANCE OF STREPTOCOCCI THAT RESEMBLE DIPHTHEROIDS RECOVERED FROM BLOOD CULTURES IN SUBACUTE BACTERIAL ENDOCARDITIS\*

JOHN A. FERGUSON, M.D., THOMAS P. MURDOCK, M.D., AND  
HENRY WELCH, PH.D., HARTFORD, CONN.

AN ASTONISHING change in size and shape of streptococci may be noticed under different conditions of cultivation.<sup>1</sup> At times these changes result in forms that have a distinct resemblance to the diphtheroid group of bacilli. In old cultures the changes that take place are probably best interpreted as "involution forms." The term "diphtheroid" is applied to an ill-defined group of bacilli, largely on account of their morphologic resemblance to the diphtheria bacillus. In this article the terms "diphtheroid" or "diphtheroid appearing" are used because of the morphologic resemblance of the organisms studied to the diphtheria bacillus and do not specify any particular bacterium.

Jensen and Morton<sup>2</sup> have, from a case of acute cystitis, isolated a streptococcus that under certain conditions resembled a diphtheroid bacillus. They speak of the organism as having a diphtheroid and a streptococcus phase.

Tow and Wechsler<sup>3</sup> have reported a case of acute endocarditis in a girl eleven years old in which diphtheroids were recovered from the blood during life and at autopsy. One year prior to the onset of the acute illness the girl had pain in the right knee and fever which lasted one week. Eight blood cultures during the course of the disease were negative, and the ninth was positive for a diphtheroid organism. Sections of the vegetations taken at autopsy showed cocci in pairs and groups. The vegetations were not cultured. In their conclusion Tow and Wechsler state that the existence of diphtheroid endocarditis is problematical and that it is likely that the streptococcus was the etiologic agent and the diphtheroid a secondary invader.

According to Thomson and Thomson<sup>4</sup> "true diphtheroids" do not show streptococcal forms in broth cultures. If this statement is true then it is of unusual interest to find diphtheria-like forms and typical streptococci in smears from uncontaminated young broth cultures from the blood of a patient suspected of having subacute bacterial endocarditis; further to find similar forms in a (Gram-Weigert) stained section from the vegetations on the heart valve when the patient came to autopsy.

## REPORT OF CASES

CASE 1.—*History:* L. H., twenty-three years of age, admitted to The Meriden Hospital, Jan. 31, 1933, complaining of weakness and fever. Had rheumatic fever in 1921. About two weeks prior to admission, patient had grip, on fifth day pain developed in right shoulder,

\*From the Departments of Pathology and Medicine of The Meriden Hospital, Meriden, Conn., and the Bureau of Laboratories of the Connecticut State Department of Health.  
Received for publication, December 2, 1933.

and persisted for three or four days, then disappeared. Had one attack of nosebleeding before admission. Had severe headache. Had palpitation and dyspnea occasionally. *Examination:* Throat slightly injected. Tongue coated. X-rays showed one abscessed tooth. Heart enlarged to the left; the point of maximum impulse was in the sixth interspace anterior axillary line. A presystolic thrill was felt. Diastolic murmur along the left border of the sternum most marked at the apex and referred to the left axilla. Lungs were clear. Spleen was felt at the costal margin. On February 14, embolic spots were found on finger tips. February 18, abscessed tooth was extracted. From this was cultured nonhemolytic, green pigment-producing streptococcus.

In view of favorable reports by Brody and Crocker,<sup>5</sup> Gordon,<sup>6</sup> Stephenson<sup>7</sup> and Howell, Portis and Beverly,<sup>8</sup> an immunotransfusion was decided upon. A vaccine was prepared from the organism found in the patient's blood stream. A suitable donor was given six injections of the vaccine subcutaneously, and one injection intravenously. Following the last injection he had a severe reaction with chills and fever.

Fig. 1.

Fig. 2.

Fig. 1.—Shows enormous masses of bacteria in the vegetation on the aortic valve. Gram-Weigert stain.  $\times 100$ .

Fig. 2.—Section from the vegetation on the aortic valve stained by Gram-Weigert method. Shows an abundance of diphtheroid organisms and one chain of streptococcus.  $\times 1000$ .

Six days after the last injection was given to the donor, the patient was given 300 c.c. of whole blood. Following transfusion he developed cyanosis, dyspnea, and cough. This critical condition persisted for several hours. He was slightly dyspneic for two or three days. From then on his condition became gradually worse, and he died on March 20. The temperature was irregularly high, ranging from  $90^{\circ}$  to  $104^{\circ}$  from admission until four days before death, when it fluctuated between  $96^{\circ}$  and  $98^{\circ}$ .

*Laboratory Observations:* Wassermann negative. Blood nonprotein nitrogen 24 mg. Blood sugar 120 mg. Several blood counts were done. The erythrocyte count varied between 4.4 millions on February 1 to 3.6 millions on March 6. The leucocytes ranged from 12,200 on February 1 to 16,600 on March 6. The differential remained fairly constant. Hemoglobin 75 per cent; polymorphonuclear neutrophils 74 per cent; small lymphocytes 17 per cent; large lymphocytes 12 per cent. The blood culture was positive.

## AUTOPSY

*Gross Observations:* Well-developed and nourished adult male. Petechiae observed on extremities and abdomen. Finger nails, lobes of ears and lips deep bluish in color. Each pleural cavity contained about 500 c.c. of clear, straw-colored fluid and a few flakes of fibrin.

*Heart:* Weighed 500 gm. The myocardium was soft and pale. The pulmonary and tricuspid valves appeared normal. The free margin of the mitral valve was slightly thickened and whitish in color. There were three pale grey, friable vegetations measuring 0.3 cm. in height by 0.3 cm. in diameter at the base of the right cusp of the mitral valve. The vegetations were located on the ventricular surface of the valve. The columnae carnae were flattened and some chordae tendineae showed slight fibrosis. The cusps of the aortic valve were obscured by a large, pale grey, friable vegetation. All the cusps were involved. The great mass of the vegetation was on the ventricular surface of the valve. The cusps were not ulcerated, although they were considerably distorted in shape. The remaining organs showed the usual appearance as found in subacute bacterial endocarditis.

Fig. 3.—Smear from broth culture which was planted from a blood agar plate. Shows a marked predominance of long chain streptococcus.  $\times 1000$ .

## MICROSCOPIC EXAMINATION

Section through the aortic valve showed a massive vegetation composed of polymorphonuclear leucocytes, fibrin, platelets, red blood cells, and dark blue staining masses of bacteria. A Gram-Weigert stained section from aortic valve showed great masses of cocci in chains and diphtheroid appearing organisms. The microscopic examination of the remaining organs showed nothing of special importance.

*Summary:* The important findings in this autopsy were vegetative endocarditis involving both aortic and mitral valves, multiple petechiae over the body, infected infarcts of the spleen, chronic passive congestion of the liver and acute congestion of the lungs, spleen, and kidneys.

*CASE 2.—History:* F. G., unmarried female, nineteen years of age, was a dramatic art teacher. The significant features in the past history were scarlet fever at seven and chorea at ten years of age. Her last illness began in September, 1932, when she complained of pain in hips and ankles and went to bed for three weeks at home. On getting up she had pain in her back and had an enlarged liver and spleen.

She was a patient in the New Haven Hospital, New Haven, Conn., in November, 1932. A blood culture on Nov. 3, 1932, was positive for diphtheroids. The patient left the New Haven Hospital in December, 1932, against advice. The diagnosis on the record was ?

subacute bacterial endocarditis.\* She was admitted to the Meriden Hospital, Dec. 29, 1932, and discharged Jan. 14, 1933, on request of the family. During this period four blood cultures were taken with negative results. Following discharge from the hospital, patient was admitted several times for blood transfusions and usually remained in the hospital a day each time. On April 25, 1933, a blood culture was positive for diphtheroids. The bacteriology of these diphtheroid-like organisms was similar to the bacteriology of those described in the case reported above. Patient died in May. An autopsy was refused.

#### BACTERIOLOGIC STUDIES

Three cultures were studied in this series. The first (laboratory number 3,674) was isolated from a blood culture during life in patient in Case 1, the second (laboratory number 7,038) was isolated from heart's blood at autopsy; the third (laboratory number 14,722) was isolated from blood of patient in Case 2 during life. After isolation several platings on blood agar were made and in each instance single colonies chosen to rule out possibility of contamination. Culture (laboratory number 14,722) was the same in all respects as Culture 3,674, so for the sake of brevity a description of the experimental studies on this culture are omitted.

*Morphology.*—The morphology of all three cultures was studied when grown on Loeffler's medium, blood agar plates (both aerobic and anaerobic) and in Douglas broth.

On Loeffler's medium culture 3,674 was a mixture of gram-positive streptococci in association with diphtheroid, bacillary-like forms (narrow, club-ended, and granular). There was a tendency for the latter forms to decolorize with the Gram stain. Culture 7,038 was similar microscopically except that the streptococci and paired forms predominated in young cultures. Cultures five days old, however, showed many diphtheroid forms.

The growth on blood agar plates of Culture 3,674 (aerobic and anaerobic) was fine and veil-like in character. In forty-eight hours a small zone of hemolysis appeared. By repeated incubation at 37° C. followed by refrigeration, secondary hemolytic rings were developed. The hemolysis was typical of the alpha variety.<sup>9</sup> Both diphtheroid and streptococcus forms were demonstrated microscopically.

The beta type of hemolysis was produced with Culture 7,038 when grown on blood agar plates either aerobically or anaerobically. Individual colonies were larger than with Culture 3,674 and showed wide, clear zones of hemolysis. After a series of eight daily transplants a few alpha type colonies developed which retained their alpha characteristics on subculture. Both diphtheroid and streptococcus forms were demonstrated microscopically.

Transplants to Douglas broth caused practically complete change to the streptococcus phase of both Cultures 3,674 and 7,038 regardless of whether inoculum was obtained from Loeffler's slants or blood agar plates. Continued daily transplants over a period of forty days were made and without exception a pure culture of long-chained streptococci (16-18 cocci to a chain) was obtained. The streptococci remained constant in their morphology for three

\*We are indebted to the Department of Internal Medicine of Yale University for permission to use data from records of the New Haven Hospital.  
The microphotographs were taken by Mr. Jean Kiefer of The Norwich Tuberculosis Sanatorium.

to four days. Usually between the fifth and seventh day diphtheroid forms could be demonstrated microscopically as the chains of streptococci appeared to have changed to the diphtheroid phase. Transplants at this point to fresh Douglas broth, however, again resulted in a pure culture of streptococci. There was a general trend toward the diphtheroid phase in cultures as they grew older. In no instance was the reverse of this phenomenon noted in any medium upon aging.

*Biochemical Reactions of 3,674 and 7,038.*—Both cultures were inoculated into 1 per cent sugar broths from Douglas broth, Loeffler's slants, and blood agar slants. Sugar broths were sterilized by filtration. Both cultures, 3,674 (alpha hemolytic) and 7,038 (beta hemolytic), gave similar reactions: Dextrose, lactose, sucrose, salicin and maltose were fermented with the production of acid. Mannite, rhamnose, arabinose and raffinose were not affected although definite growth was obtained. In litmus milk, acid and coagulation was produced. On the basis of the morphologic and biochemical reactions Culture 3,674 would be classified as a strain of *Streptococcus viridans*, variety probably *mitis*. Culture 7,038 would be classified as a strain of *Streptococcus hemolyticus*.

#### SEROLOGIC STUDIES

In order to augment our findings both cultures were sent on blood agar slants to the Rockefeller Institute\* for further study. The following report was obtained:

"Culture 7,038 seems to be a typical hemolytic streptococcus. A precipitin test with an extract of the organism shows that it contains the carbohydrate 'C,' characteristic of strains of human origin (Group A).

"Culture 3,674 seems to be a typical *Streptococcus viridans* and not merely a non-hemolytic form of 7,038, since extracts of 3,674 do not show any traces of the 'C' substance characteristic of hemolytic streptococci belonging to Group A."

After several weekly transplants on Loeffler's slants and blood agar plates, Culture 3,674 developed colonies which showed typical beta hemolysis. When single colonies were chosen and plated on blood agar, however, both alpha and beta type colonies developed. Morphologically and biochemically both types of colonies (alpha and beta) agreed with the colonies obtained from Culture 7,038 (alpha and beta). These four cultures were then sent to the Rockefeller Institute and tested for the group carbohydrate "C." The two beta hemolytic strains both gave precipitin reactions with anti "C" serum for Group A and no reaction with anti "C" serum for any of the other groups. The two alpha hemolytic strains did not react with any of these sera. From these studies it is obvious that the colonies showing alpha hemolysis are antigenically distinct from those showing the beta type.

#### COMMENT

The interesting features of the case clinically were: the reaction following transfusion with a specifically immunized donor; and the blood culture studies.

\*The authors are indebted to Dr. R. C. Lancefield for these studies.

Two possibilities present themselves as probable causes of the severe reaction following immunotransfusion. First, the occurrence of a pulmonary embolus following the transfusion, always a possibility, must be considered. Second, the interaction between the antibody of the donor and antigen of the recipient. Of these two possibilities, the latter appears to us to be the more likely. The patient's tissues were proliferated with antigen. Both the streptococcus and diphtheroid phases were demonstrated in tissue section at autopsy. The donor received both phases in the vaccine used for production of the therapeutic serum. With a preponderance of antigen in his tissues, the recipient was in a highly sensitive condition and the violent reaction following transfusion with whole blood containing antibody was probably due to an antigen antibody complex in the tissues and blood stream of the patient. The clinical picture of cyanosis, dyspnea and cough directly following the immunotransfusion would appear to augment this theory.

Jensen and Morton's<sup>2</sup> experiments with the diphtheroid phase of a streptococcus isolated from a case of acute cystitis led them to believe that the diphtheroid phase was nonpathogenic. We are carrying on experiments at the present time that appear to show that in rabbits the diphtheroid phase is pathogenic in the sense that definite valve localization can be produced. At this time, however, we wish to suggest the possibility that in certain instances, in subacute bacterial endocarditis, it is the attenuated diphtheroid phase of the streptococcus that first becomes implanted on the heart valve. Once a small clot is formed on the valve the medium is perhaps suitable for the change of the organism into the streptococcus phase following which the disease progresses in the usual manner.

In a study of 1,079 blood cultures Thompson<sup>10, 11</sup> has shown the presence of diphtheroids in 3 per cent of those examined. His object was to test the hypothesis advanced by Koch and Mellon<sup>12</sup> that diphtheroids are found in the blood stream in persons convalescent from streptococcal infections. Thompson believes that diphtheroids in blood cultures appear to have the same significance as the saprophytic cocci.

Thompson<sup>10, 11</sup> states that "Any organism which appears as rods, and which in subcultures in broth develop chains of streptococci may better be classified as streptococci, especially if it is not possible subsequently to bring about the reverse change from the streptococcal to the rodlike form." The organism numbered 3,674 in this investigation originally showed a majority of diphtheroid forms and subsequently developed into a streptococcus, but we have been able to change this organism back to the diphtheroid phase at will by the use of proper media.

If we accept the hypothesis of Thomson and Thomson<sup>4</sup> the organism would have to be classified as a streptococcus with a diphtheroid phase. However, whether we regard this phenomenon as one of pleomorphism or not is not our basic interest. We are primarily interested in focusing attention on the significance of the finding of diphtheroid appearing organisms in blood cultures, particularly in cases of subacute bacterial endocarditis.

Grinnell<sup>13</sup> reports that he was able to obtain from single cell strains of *Streptococcus hemolyticus*, strains of *Streptococcus viridans* with constant char-

acteristics. He notes "the alpha variants remain true to type, the loss of hemolytic power is accompanied by a slight loss of virulence, the alpha derivatives usually but not always give the same fermentative reactions." In this investigation we were able to confirm these results. The alpha variants from the beta hemolytic types were antigenically distinct although giving identical fermentative reactions.

Our experiments on animals to date have shown definitely that the organism has very low virulence. Large quantities, regardless of the phase, when injected into rabbits produce no toxic effect. However, by repeated injections of any of the three phases over a period of from twenty-three to thirty-five days definite localization has been demonstrated. This section of the investigation has not yet been completed.

#### SUMMARY

1. Two cases of subacute bacterial endocarditis are described in which diphtheroid appearing organisms were recovered repeatedly from blood cultures during life.

In Case one, Gram-Weigert stained sections from the vegetation on the aortic valve at autopsy showed both diphtheroid appearing forms and chains of streptococci in each section. Bacteriologic investigation in both cases showed that the streptococcus under study existed in two phases, a typical streptococcus phase and a diphtheroid phase.

2. As a result of the bacteriologic studies of the two cases reported in this paper evidence is submitted which shows that the occurrence of diphtheroid appearing organisms in blood cultures from suspected cases of subacute bacterial endocarditis must be regarded as important. The organism, isolated from blood cultures in the diphtheroid phase, changed under suitable conditions into a green producing streptococcus which is unquestionably of etiologic significance.

# THE USE OF GALACTOSE IN THE DIFFERENTIAL DIAGNOSIS OF JAUNDICE\*

## A PRELIMINARY REPORT

KENNETH A. OWEN, M.D., CLEVELAND, OHIO

IN A SURVEY of the literature concerned with the physiology of the liver and the tests devised to estimate its functional capacity,<sup>1, 2, 3, 4, 5, 6</sup> it is noteworthy that until recently very little of clinical value has been accomplished either in the diagnosis or in the prognosis of liver disease.

There are several reasons for this. First, the liver is a huge organ, the site of multiple activities, and has been aptly called "the great storage battery of the human body." It is obvious, therefore, that no one test is likely to yield an accurate index of its total functioning capacity. Furthermore, experimental work has shown that there is a tremendous hepatic reserve, a reserve greater probably than in any other organ of the body. To quote from the report of Bollman and Mann on lesions of the liver produced experimentally in dogs:<sup>5</sup> "It would appear that any test, capable of measuring the metabolic changes which depend entirely on the liver, would give an accurate index of the efficiency of this organ. There are several reasons why such tests show but little, and studies of animals from which the liver has been partially removed reveal some of the reasons for the failure of those tests. In the dog and in many other animals, the liver consists of several distinct lobes, one or more of which may be successfully removed. Immediately following such operations, the remaining portions of the liver begin to hypertrophy, and by serial operations, removing a lobe of liver every few weeks, it is possible to remove more hepatic tissue than was originally present and still have a normal amount of hepatic tissue remaining in the dog. During this process no signs of hepatic insufficiency are observed except a transient upset of a few days' duration, which is probably due to injury of its remaining hepatic tissue rather than to actual deficiency because of removed tissue. . . . It is obvious that less than 20 per cent of liver can accomplish the work of the entire organ."

Second, the main effort and emphasis in the study of this problem from the laboratory standpoint have been expended on attempting to estimate the excretory capacity or permeability of the liver by the use of various dyes—in a way analogous to the dye tests of renal function. As a result of this, the bromsulphalein and rose bengal tests have come into general clinical use. Their value is indeed very limited, for while the rate of their elimination from the blood stream and excretion by the liver may give some information as to the permeability of the liver and the patency of its biliary system, it helps not at

\*From the Cleveland Clinic.

Received for publication, January 3, 1934.

all in estimating the ability of the liver to perform its more vital functions. Foremost among these may be mentioned the conversion of sugar to glycogen, its storage and release again into the blood stream as glucose; the synthesis of urea; the formation of bile pigment and the detoxification of poisons.<sup>6</sup> The dye excretion tests do not indicate the capacity of the liver to perform these functions; and furthermore, when either intrahepatic or obstructive jaundice is present, the estimation of dye in the plasma is bound to be inaccurate, yielding a value which is almost always too high.

Tests of pigmentary function of the liver, of which the van den Bergh test is outstanding, have been of no help in determining the nature or extent of liver damage and have failed particularly in the differentiation of obstructive and intrahepatic jaundice. In recent years, the rate of removal of bilirubin injected intravenously has been used as a test of liver function as reported by Bergmann in 1927 and by Harrop and Barron in 1931.<sup>7</sup>

Estimation of the cholesterol content of the blood plasmas in cases of hepatic and biliary disease has been reported recently in an excellent article by Epstein.<sup>8</sup> This promises to be a valuable means of estimating liver damage.

Since the discovery of the glycogenic function of the liver by Bernard about the middle of the last century, many reports have been published in the literature on the utilization of various sugars for testing hepatic function. These investigations have been productive of widely divergent results and interpretations, due to the fact that the tests were not standardized, that they were used in all varieties of liver disease, and that no allowance was made for the properties of great reserve and rapid regeneration which we now know to exist. In short, extensive acute or subacute damage to the liver must be present before changes are reflected by a derangement of carbohydrate metabolism.

In this report, I shall confine the discussion to that puzzling group of cases of relatively painless acute jaundice in which neither the history, physical signs, nor laboratory reports make the diagnosis clear. These cases may be due to common duct obstruction of one sort or another or may be caused by acute or subacute diffuse liver damage, such as occurs in catarrhal icterus or toxic hepatitis.

Recently a modification of the glucose tolerance test has been used with some success to estimate the liver function by workers at the University of California.<sup>9</sup>

Keeping in mind the functional complexity of the liver, its great reserve and power to regenerate rapidly, and the present inadequacy of the tests in general use to determine its "vital capacity," the problem of jaundice and its differential diagnosis by means of galactose tolerance may be considered.

This differentiation has often confused the keenest clinicians, yet it is of the utmost practical importance to the patient, since the therapeutic measures are diametrically opposed. Extrahepatic obstructive jaundice is a surgical problem. In jaundice due primarily to inflammation or degeneration of the liver parenchyma, surgery is positively contraindicated. The galactose tolerance test of liver function furnishes a simple and positive means of making this differentiation.

## USE OF GALACTOSE

About thirty years ago the use of levulose as a test for liver function was attempted by Strauss, and five years later Richard Bauer of Vienna began to use galactose for the same purpose.<sup>10</sup> Since that time levulose, dextrose, and fructose all have been proposed and tried as tests of the carbohydrate metabolism of the liver with little success. Galactose, which appears to be the most valuable of the monosaccharides for this purpose, has received but little attention in this country.

In 1931 several papers were published by Shay, Schloss, Bell, and Rodis of Philadelphia outlining the theoretical considerations for the use of galactose as a test of liver function<sup>11</sup> and also their results in cases of jaundice.<sup>12</sup> The work here reported was done in order to confirm or deny their findings.

From a theoretical standpoint, in considering the use of any carbohydrate as a test for liver function, galactose seems best suited for this purpose. First, the sugar must be pure and stable. When given orally it must be absorbed from the gastrointestinal tract easily and with little decomposition by bacteria. It must be capable of transformation by the liver into glycogen, preferably with difficulty; the normal tolerance for the sugar must be known; and finally, there must be a stable renal threshold.

Galactose may be obtained in a pure form, though it is rather expensive. It is rapidly absorbed from the gastrointestinal tract, and, according to present knowledge, it is utilized *only* by the liver and that with difficulty. It is well known that the other sugars have no such specificity. Furthermore, experimental work has shown that after reaching the general circulation it is all excreted by the kidneys, regardless of the condition of the other glands. There is no renal threshold for galactose.<sup>11</sup>

Since the liver has such adequate reserve and such power for rapid regeneration, it is clear that in local or slowly progressive liver disease there is no change in the carbohydrate metabolism. But it is equally obvious that marked derangement of carbohydrate metabolism might be expected when there is extensive acute or subacute damage to the liver cells or when chronic damage has gone on to such a stage that regeneration fails. The variable results which have attended many types of tests for the function of sugar metabolism may be explained partly on this basis. In other words, the test has definite limitations, and it is these very limitations which make it valuable in the differential diagnosis of jaundice. The galactose tolerance test of liver function serves to identify and differentiate those cases of diffuse liver damage which occur in toxic or infectious jaundice from those cases of jaundice due to obstruction of the bile ducts.

## TECHNIC OF THE GALACTOSE TOLERANCE TEST

The work of Shay and Schloss has shown that the normal liver, regardless of age, sex or condition of the other glands, can metabolize about 40 grams of galactose. That portion not stored by the liver appears in the urine as a reducing substance, identified chemically and polariscopically as galactose. In their series of normal persons, this output varied from 0 to 3 grams.

The test is carried out as follows:

1. A fasting specimen of urine is obtained.
2. The patient is given 40 grams of pure galactose, dissolved in one pint of water.
3. Breakfast is omitted.
4. All urine voided in the next five hours is collected, preferably in hourly specimens.
5. The specimens are tested qualitatively for galactose and all those positive are lumped in one volume and tested quantitatively by the Benedict method. (In diabetic patients it is possible to eliminate glucose by the process of fermentation with yeast, as galactose is relatively stable.)

In Table I are listed the series of normal values prepared by Shay and Schloss and my own series of normal values, obtained by the same technic. In respective columns are given the ages of these persons in years, their weight

in pounds, and the amount of galactose found in the urine during the five hours following ingestion.

It is seen in these two series containing sixty normal cases that the average urinary output of galactose is less than 1 gm. The highest output in the first series was 2.2 gm. and in my series, 2 gm.; while the great majority of normal persons excreted less than 1 gm.

From these observations it seems safe to state that an output of 3.0 gm. or more is abnormal. In my series it has been found invariably that in normal persons galactose, if excreted at all, appears in the first and second specimens and rarely is found in the later specimens.

At the Cleveland Clinic, galactose has been used as a test of liver function for over a year. The results of this investigation may be summarized as follows: From the standpoint of the amount of galactosuria, the patients tested fall into two general but rather definite groups. In those excreting *abnormal* amounts of galactose, the clinical impression pointed toward diffuse liver damage; in those with a *normal* output, clinical investigation or subsequent exploration revealed the jaundice to be due to biliary obstruction. A summary and comparison of clinical and operative findings with the results of the galactose tolerance test are presented. (Table IIA and IIB.)

In the first group of undoubted cases of biliary obstruction, the galactose test, prior to operation, showed in each of these a normal secretion, averaging 0.87 gm.

In the second group, however, in which the diagnosis of diffuse liver damage is reasonably certain, marked galactosuria ranging from 1.90 to 9.1 gm. (average over 5 gm.) was present. These results correspond very well with the observations of Shay, Schloss and Rodis.<sup>12</sup>

A review of the histories of several of these patients gives some impression of the value of the test in differential diagnosis.

CASE 1.—A man, aged fifty-four years, was admitted to the hospital, complaining of hunger pains, itching, and jaundice of one week's duration. The past history was irrelevant except that he had noticed a gradually increasing epigastric pain before meals during the preceding year. Physical examination revealed moderate, generalized icterus, fair nutrition, and an enlargement of the liver, which was described as being 6 cm. below the costal margin, rough, irregular, and not tender. The cholecystogram showed a nonfunctioning gallbladder. The bromsulphalein test showed 80 per cent retention of dye in one-half hour. The clinical diagnosis was "common duct obstruction, probably stone." The galactose test showed an output of 1.8 gm., corroborating the impression of obstruction. Operation revealed an inoperable cancer at the head of the pancreas.

CASE 2.—The patient, a man, aged forty-two years, was admitted to the clinic, complaining of indigestion, belching, progressively increasing jaundice, and the loss of 10 pounds in weight in the course of three weeks. The patient had had several phallic sores and a positive blood Wassermann two months before, for which he had had no treatment. The patient was well nourished, moderately jaundiced, with a slow pulse rate and slight tenderness over the right upper quadrant. The liver was palpable 3 cm. below the costal margin. The Wassermann test was weakly positive, the bromsulphalein test showed a retention of 30 per cent in half an hour and the galactose test an output of 3.3 gm.—confirming the clinical impression of catarrhal jaundice or syphilitic hepatitis.

CASE 3.—A housewife, aged twenty-six years, came to the clinic complaining of jaundice, weakness, and itching. Four years before, the gallbladder had been removed. Two years

\*Intermittent.

later the patient had jaundice and was operated on again. At that time a small stone was removed from the common duct with subsequent drainage of bile for ten weeks after the operation. Eight months previous to her visit to the clinic, jaundice again had appeared in intermittent attacks with recurrent pain in the left upper quadrant, which pain had persisted. Examination revealed emaciation, generalized icterus, and a large tender liver, with questionable splenic enlargement. The patient had a slight fever, and a slow pulse rate.

The bromsulphalein test showed 60 per cent retention in one-half hour. The icterus index was 75. The clinical impression was that the jaundice was due either to common duct stone or to adhesions. The galactose test showed a normal excretion of 0.63 gm. At operation the common duct was found occluded by adhesions. The liver was normal.

CASE 4.—A woman, aged thirty-two years, was admitted to the hospital complaining of jaundice and weakness and with the story of having had nausea and vomiting, recurrent dull pain in the right upper quadrant, and progressive jaundice of three weeks' duration. Physical examination revealed a poorly nourished young woman with moderate icterus and tenderness over the right lobe of the liver. The cholecystogram showed a functioning gallbladder. The van den Bergh test was direct; the serum bilirubin was 5.8 gm. The clinical impression was "stone in the common duct." The galactose test showed an output of 4.1 gm.—indicating an intrahepatic process, rather than obstruction of the duct. Operation for stone did not disclose any obstruction. The appendix was removed, and the patient recovered uneventfully.

This is an excellent example of the value of the galactose test before operative procedures are considered too hastily.

CASE 5.—A dentist, fifty-six years of age, was admitted to the hospital complaining of weakness and slight indigestion for three months. Three weeks before admission he had begun to experience vague epigastric distress and pain in the right upper quadrant, some nausea and clay-colored stools and, ten days before admission, the development of a steadily deepening jaundice. The physical examination revealed generalized icterus, fair nutrition, normal temperature, and a large, tender liver. The gallbladder was nonfunctioning, according to the roentgenogram. The bromsulphalein test showed a retention of 100 per cent, the serum bilirubin was 20 mg., and the galactose output on two occasions was 7.0 and 6.5 gm., respectively. There was much debate as to the nature of jaundice in this case. Operation was seriously considered, but since the jaundice seemed to be subsiding, this was abandoned. The galactose test revealed that the cause of jaundice was intrahepatic, probably of catarrhal nature, and not obstructive.

In reviewing these five representative cases, it is evident that the ability or failure of the liver to metabolize the galactose has given valuable negative evidence as well as positive findings in cases in which operative interference has been considered.

From the standpoint of prognosis, the test also is of value. Several of the patients with catarrhal jaundice or toxic hepatitis have had subsequent galactose tests and concomitant with clinical improvement, and in several instances even before improvement was obvious clinically, the excretion of galactose gradually fell to normal. These patients all recovered. (Table III.)

It has been of interest to review in the literature the cases studied with this test. In his early work, Bauer thought that he had found a test for cirrhosis of the liver. Two years later he reported the finding of an alimentary galactosuria in catarrhal jaundice and described ten such cases showing galactosuria which gradually decreased as the patients improved.<sup>13</sup> He considered an output of more than 3 gm. as indicating a pathologic condition of the liver.

In the comparative series of cases recently published by Shay, Schloss and

Rodis, an output of galactose of more than 3 gm. was considered indicative of liver damage, and these authors expressed the thought that the element of chance may work against the test in both of these types of cases. For in mild catarrhal jaundice or hepatitis the carbohydrate metabolism may be only slightly altered and may tend to rapid recovery, while in the other group in which there is chronic damage to liver cells, destruction may progress to a state of diffuse involvement. It is also known that a so-called catarrhal jaundice or hepatitis may complicate the course of a chronic liver disease, such as cirrhosis.

In the series here reported, I have seen and listed several such instances of advanced cirrhosis with ascites and the terminal development of jaundice. In all of these cases, there was an abnormal excretion of galactose. In the average uncomplicated case of cirrhosis, however, assuming that only fibrosis is present, it is obvious that the carbohydrate metabolic function of the liver is normal and that only the permeability or excretory function is deranged. (Table IV.)

| 52  | Toxic hepatitis    | Jaundice (2 months)         | Operation<br>Pathologic section | 80-80%           | trace               |

To recapitulate—practically all of the cases which have been reported as showing an abnormal excretion of galactose fall into the group in which it is reasonable to believe that a relatively acute diffuse liver damage has taken place. Among these may be listed cases of catarrhal jaundice, arsphenamine hepatitis, phosphorous poisoning, acute yellow atrophy, syphilitic hepatitis, and the hepatitis of infection or intoxication, such as is occasionally seen in pneumonia or hyperthyroidism.

In conclusion, it seems that the galactose tolerance test of liver function furnishes a simple but valuable procedure which clearly identifies and differentiates the toxic or infectious type of jaundice from the jaundice due to extrahepatic causes.

## THE DETERMINATION OF SERUM PROTEIN BY MEASUREMENT OF THE VOLUME OF PRECIPITATE\*

---

FLORENCE W. HAYNES, PH.D., BOSTON, MASS.

---

THE protein content of urine and cerebrospinal fluid is commonly determined by the measurement of the volume of protein precipitated by certain reagents. Shevky and Stafford<sup>1</sup> compared previous clinical precipitation methods for protein and developed a more accurate one, using Tsuehiya's reagent. This method has been used and modified by McNaught<sup>1</sup> for cerebrospinal fluid and by MacKay (Peters and Van Slyke<sup>2</sup>) for urine. Samson<sup>3</sup> has presented a micro-precipitation method for serum protein as well as for serum albumin and globulin but does not give figures for the absolute amounts of protein in either case or compare his values with those of other standard methods. In the hope of making available a simple clinical method for blood protein, comparative determinations have been made both by the precipitation and by macro-Kjeldahl methods.

### TECHNIC

The procedure adopted was that given for urine by MacKay with the exception that the volume of protein precipitated was compared with the volume of precipitate from a standard casein solution (McNaught). For this standard a solution containing 3.0 gm. casein, 1.0 gm. sodium bicarbonate, 25.0 gm. sodium chloride, and 20 c.c. formalin was made up to a liter and filtered. The nitrogen was then determined by the Kjeldahl method. Such a standard keeps indefinitely at room temperature. The serum was diluted 1 to 50 and 1 to 75 with 2.5 per cent sodium chloride. Four-cubic-centimeter amounts of diluted serum were put in Shevky-Stafford tubes, two tubes being used for the standard, two for the 1-to-50 dilution, and two for the 1-to-75 dilution. The volume of precipitate was thus brought into range with the volume from the standard. Tsuehiya's reagent (1.5 gm. phosphotungstic acid and 5 c.c. concentrated hydrochloric acid made up to 100 c.c. with 95 per cent alcohol) was added up to the 6.5 mark; the tubes were then inverted slowly three times and, after exactly ten minutes, centrifuged for ten minutes at 1,800 revolutions per minute.

---

\*From the Thorncliffe Memorial Laboratory, the Second and Fourth Medical Services (Harvard) of the Boston City Hospital.

Received for publication, November 9, 1933.

Calculation was made as follows:

$$\frac{\text{Vol. ppt. unknown}}{\text{Vol. ppt. standard}} \times \frac{\text{Grams \% protein in standard}}{\text{Dilution of unknown}} = \text{Grams \% protein in unknown serum}$$

## EXPERIMENTAL RESULTS

Results by the above method are shown in Table I.

The procedure used was adopted as the result of numerous attempts to make the precipitation method accurate for serum. It was found unsatisfactory merely to multiply the volume of precipitate by the dilution and by the factor 0.72, as is done to obtain the amount of protein in urine. Values for serum protein thus obtained vary with the dilution and with uncontrolled changes in the speed of the centrifuge. Therefore a standard protein solution was used. Various modifications, as the use of sodium tungstate precipitation, the use of different standards (horse serum, human serum, albumin, and casein as shown in Table II), a longer period of centrifuging and dilution of the serum and

standard with different concentrations of saline have been tried in attempts to make the method more accurate. Results with different concentrations of saline are shown in Table III.

TABLE III

| CONCENTRATION OF SALINE | AVERAGE PERCENTAGE ERROR |
|-------------------------|--------------------------|
| 0.8%                    | +6.5                     |
| 1.0%                    | +4.0                     |
| 1.5%                    | +4.1                     |
| 2.5%                    | -4.0                     |

In a few cases the precipitates were resuspended in 80 per cent alcohol and recentrifuged. Considerable variation in the volumes of precipitate in duplicate tubes was found in all of these modifications. For example, five volumes of precipitate from the same solution, centrifuged at the same time, varied in one case from 0.175 to 0.190 c.c. of precipitate. In the later determinations it was thus considered necessary to compare duplicate tubes on all samples.

From the tables it may be seen that the majority of the results have an error of less than 5 per cent although they may occasionally vary from the Kjeldahl determination by as much as 12 per cent, especially when the amount of protein is small.

The average percentage error (+6.5 to -4.0 per cent) compares favorably with the error found by Shevky and Stafford<sup>4</sup> for urine (average error, 8.4 per cent; standard deviation,  $\pm 9.7$  per cent). The results obtained by McNaught<sup>1</sup> on cerebrospinal fluid are, however, somewhat more accurate (1.5 to 5.1 per cent error). It is recognized that an inherent error exists in methods based on the precipitation of colloids, the physical state of which may vary in different ex-

## HAYNES: DETERMINATION OF SERUM PROTEINS

periments. Factors which affect such precipitation have been discussed by Samson.<sup>3</sup> Of these, the ones which have not been controlled in the present determinations are the size and specific gravity of the particles precipitated, the specific gravity and viscosity of the fluid in which precipitation takes place, and to some extent the temperature of the system.

## SUMMARY

A simple method for the determination of serum protein is presented and discussed. The volume of protein precipitated from diluted serum by a photungstic acid reagent has been measured in Shevsky-Stafford tubes and compared with the volume from a standard protein solution.

With the proper standard at hand, the simplicity and speed of the precipitation method and the small amount of equipment needed, as compared with the Kjeldahl determination, make the precipitation method applicable for clinical use.

## THE REFINING OF ANTISERUMS\*

A. J. KLEIN, CHARLES K. GREENWALD, AND K. GEORGE FALK, NEW YORK, N. Y.

### INTRODUCTION

THE method of refining and concentrating antiserums and antiplasma which is used in this laboratory will be described in this paper. This method is being used for antipneumococcus and antimeningococcus serums and in modified form for other serums. The experimental procedure will first be outlined; then modifications and explanations of the procedure will be given; and finally a brief discussion and summary of the relations will be presented.

### EXPERIMENTAL PROCEDURE

The method to be described is that used primarily for refining pneumococcus antiserums.

a. *Preparation of Serum.*†—Immediately after the separation of the serum, 0.5 per cent phenol was added in the form of a solution containing five parts phenol and six parts ether.<sup>1</sup> If this immediate addition was not possible, the phenol was added as soon as practicable. The serum was kept cold. Before beginning the further treatment, the serum was tested as to sterility. If bacteria were present, the serum was filtered through a Berkefeld filter, No. N.

b. *Dialysis of Serum.*—The serum, containing 0.5 per cent phenol, was well mixed, placed in cellophane (No. 600) bags, from 3 to 4 liters in each. To each bag 10 c.c. toluene and 5 c.c. chloroform were added. Each bag was then tied tightly near the top, the top turned over and tied, or an additional piece of cellophane placed over it, in order to eliminate the possibility of contaminants dropping into the bag. Dialysis against running tap water was allowed to proceed for from five to seven days. After forty-eight hours and again after ninety-six hours, 0.2 per cent phenol (in ether) was added to each bag. The temperature of the tap water ranged from 12° to 25° C. at different times of the year. The duration of the dialysis was greater with the cooler water. The sterility of the dialysate was tested after dialysis.

c. *"Acid Protein" Precipitation.*—The dialysates were removed from the bags and mixed, the bags washed with several hundred cubic centimeters of distilled water, which were added to the main bulk. Dry sodium chloride to bring the solution to N/20 was added (2.92 g. per liter). The solution was placed in the ice box overnight. Early the next morning, it was brought to  $P_H$  5.1 with normal acetic acid ( $\gamma$  - dinitrophenol as indicator), allowed to stand in the

\*From the Bureau of Laboratories, Department of Health, New York, N. Y.

Received for publication, November 3, 1933.

†The serum was obtained from horses immunized with the centrifuged sediment of pneumococcus broth cultures taken up with saline and the vaccine killed with formalin. In general terms, the horses were inoculated three successive days, rested six days, and the series repeated with increasing dosages up to a certain maximum. Test bleedings were taken every two weeks.

cold for from four to five hours, and filtered through paper pulp and "super cel"<sup>2</sup> on a Buchner funnel until clear.

d. *Preliminary Tests for Antibacterial Substance Precipitation.*—The filtered solution was brought to  $P_H$  5.9 with N NaOH and kept in the ice box. Portions of 50 c.c. were brought to  $P_H$  5.9, 6.1, 6.3, and 6.8 (with N NaOH where necessary) (p-nitrophenol as indicator), diluted with from four to five volumes of Berkefeld filtered tap water, and allowed to stand in the ice box overnight. The next day the mixtures were centrifuged, the precipitates dissolved in one-fifth the volume (10 c.c. each) of 1 per cent sodium chloride solution, and the supernatants were tested for antibacterial substance contents by precipitin or agglutinin reactions (or both.)<sup>2</sup> In estimating the contents in this way, account was, of course, taken of the concentration or dilution of the antibacterial substance in comparison with the original serum.

These tests were carried out under the direction of Miss Georgia Cooper, who outlined the procedure as follows:

"The titrations were made with quantities of antiserum from the following range, which were selected to show the character and the end point of the reaction; 0.1, 0.05, 0.02, 0.01, 0.005, 0.002, 0.001, 0.0005, 0.0002, 0.00001, 0.00005 c.c.

"For the agglutination tests the antisera were so diluted with physiologic saline that the requisite amounts were contained in 0.5 c.c. Five-tenths cubic centimeter of each of the dilutions and 0.5 c.c. of a fresh eighteen- to twenty-hour broth culture of pneumococci were mixed in test tubes and incubated for two hours at 55° C. Readings were made. The tubes were stored in the ice box overnight and readings again made.

"For the precipitation tests 0.1, 0.05, and 0.02 c.c. of the undiluted antisera and the smaller quantities diluted to be contained in 0.05 c.c. were obtained with 0.1 c.c. of the precipitating antigens in test tubes. The tubes were rolled for two minutes. Five-tenths cubic centimeter saline solution was then added to each tube and readings were made. The precipitation antigen was prepared by growing pneumococci in phosphate beef-heart broth for about a week, at the end of which the organisms generally were found to be autolyzed. The precipitation antigens before use, when necessary, were centrifuged until clear. With certain exceptions, the end points of precipitation, and of agglutination to a lesser degree, indicated with a moderate degree of accuracy the relative amounts of mouse protective antibacterial substances in the antisera tested."

If the supernatants showed the presence of appreciable quantities of antibacterial substance (10 per cent or more of the original), in place of procedures "e" and "f" which follow, recourse must be had to procedures "e1" and "f1."

e. *Precipitation of Antibacterial Substance.*—The solution was brought to the desired  $P_H$  as found in the preliminary tests, four volumes of Berkefeld filtered tap water containing 0.2 per cent phenol added, and placed in the ice box overnight. The precipitate in general settled well. The bulk of the supernatant was siphoned off, and the rest of the liquid separated by centrifuging.

<sup>2</sup>Obtained from the Johns-Manville Corporation, New York City.

f. *Solution of Antibacterial Substance.*—The precipitate was dissolved in from one-fifth to one-tenth of the original volume of 0.5 per cent sodium chloride solution containing 0.5 per cent phenol. The amount of solvent was governed in part by the potency of the original material and the potency desired in the final product, and in part by the physical consistency (viscosity) of the material after solution. The solution was placed in the ice box for at least twenty-four hours, then filtered through super cel and paper pulp to remove separated fibrin. One per cent additional sodium chloride (solid) was added and the solution stored at low temperature.

g. *Preparation of Antibacterial Solution for Clinical Use.*—The cold solution was allowed to warm to room temperature and filtered on a Buchner funnel through paper pulp and super cel and then through a Berkefeld filter. If filtration was slow through a fine Berkefeld, preliminary filtration through a coarser (V), followed by filtration through the finer (N), was used. The filtrate was tested for sterility and then bottled in 10, 15, or 25 c.c. vials, as desired. Suitable sterility tests on the vial contents were also carried out. The preparations were kept in the ice box. At times, solid material (presumably protein) separated in the vials at the low temperature but dissolved readily again at room temperature. Since the material is warmed at 37° C. before use clinically, this separation occasions no difficulty. Stock was labelled to be returned in six months. If the solutions became cloudy, they were refiltered and rebottled, as well as retested for potency. Potency tests, either mouse or agglutination and precipitation, were carried out as described elsewhere both on the filtered bulk and on the bottled materials.

e1. *Alternative Method of Precipitation of Antibacterial Substance.*—If the supernatants of the preliminary precipitation tests "d" showed appreciable quantities (10 per cent or more) of the original antibacterial substance, the following method was used. An equal volume of saturated ammonium sulphate solution was added with thorough stirring (so-called 50 per cent saturation), allowed to stand from four to five hours, and filtered on a number of large fluted papers. This filtration was complete overnight.

f1. *Solution of Antibacterial Substance.*—The precipitate was removed from the filters, pressed between sheets of filter paper in a press for some hours, placed in a cellophane bag containing 10 c.c. chloroform, and suitably tied and dialyzed against running tap water for from three to four days. To the solution after removal from the bag, 1.5 per cent sodium chloride and 0.5 per cent phenol (as phenol-ether mixture) were added. The volume was then from one-fourth to one-half of the volume before precipitation. The solution was placed in the ice box for at least a day and then filtered through paper pulp and super cel to remove separated fibrin. Further treatment followed that described in section "g."

#### NOTES ON THE EXPERIMENTAL PROCEDURE

A. The method outlined is given as applicable to antisera. Essentially the same procedure can be used with plasma. The greater amounts of fibrin (and fibrinogen) in the latter may increase the acid, perhaps other precipitates, and may also make filtration slower and more difficult. An essential feature of

the method consists in keeping the material as free from bacterial growth as possible. The importance of this fact and the desirability of having no products of bacterial growth present in the final products was recognized early and strongly emphasized, among others by Anderson<sup>2</sup> in 1909 and by Avery and his coworkers<sup>3</sup> in 1917.

B. Dialysis of the serum was an essential feature of the Banzhaf-Klein procedure.<sup>4</sup> This procedure was stated to depend upon the observations of Avery<sup>5</sup> and of Felton<sup>6</sup> that pneumococcus antibacterial substances were precipitated from serums by dilution with distilled water. Dialysis in the Banzhaf-Klein procedure was assumed to remove the salts and so play the part that was taken by dilution. It may be stated that, as a result of dialysis and the accompanying removal of salts, partial, but not complete precipitation of antibacterial substance occurred. The function of the dialysis did not, therefore, appear to be altogether simple. In addition to removing the salts, it evidently involved changes in the character of the globulins. Such changes have been described by Svedberg,<sup>7,8</sup> who, as a result of molecular weight determinations, considered that one globulin was present in serum initially and that different treatments broke it down into fractions designated pseudoglobulin and euglobulin, and by Reiner and Reiner,<sup>9</sup> who showed that repeated precipitations resolved a globulin precipitable at a definite  $P_H$  value (from 5.5 to 6.0), into two globulins precipitable at two different  $P_H$  values (5.1 and 6.7). Dialysis evidently caused changes in the natures of the protein fractions which resulted in the subsequent procedures furnishing an immunologically useful product. It was found possible to keep the contents of the bags sterile throughout the dialysis by using the precautions given, although tests<sup>6</sup> showed that about 70 per cent of the phenol dialyzed out of the bags within the first three days. If the cellophane bags were used for more than one dialysis, they were washed thoroughly and kept in 5 per cent phenol solution until used again.

C. The "acid protein" precipitation as developed by Felton<sup>10,11</sup> was an essential part of the method. With Types I and II pneumococcus antisera it was permissible to allow the precipitate in the solution to stand overnight in the ice box; with other antisera the time should be limited to five hours because of possible inactivation due to the acid condition.

D. The preliminary tests for the best conditions for the precipitation of antibacterial substance were very essential. It was naturally desirable to obtain these conditions in as short a time as possible. Agglutinin and precipitin tests were used, therefore, and not mouse protection potencies. Comparative results were sufficient for the purposes in view, namely, possible losses of material as shown in the tests on the supernatants. A large number of pneumococcus (as well as meningococcus and other) antisera were tested, but no regularities observed as to the most suitable hydrogen ion concentration. The two best values were found to be  $P_H$  5.9 - 6.1 and  $P_H$  6.8. Apparently a number of variables, including the organism and method used in inoculating the horses, the condition and state of the horses (whether they had been bled over a long or short period of time), the keeping and handling of the serums, etc., all played a part

\*Carried out by Edward Buxbaum.

in determining the properties of the protein substances present. These conditions, at present, are not controllable. In this connection, attention may be directed again to the work of Reiner and Reiner referred to earlier in this paper. The classification of proteins to be applied to these different precipitates is not altogether clear. The "acid precipitate" at  $P_H$  5.1, is in part fibrin and possibly euglobulin; the antibacterial substance precipitate may be considered to be pseudoglobulin, since practically all anti substances have been found to be associated with this protein fraction. However, this precipitate did not include all of the pseudoglobulin present in the serum. At times, antibacterial substance was found in the supernatant from such a precipitate. In such a case, recourse was had to precipitation with 50 per cent saturation of ammonium sulphate, the customary method of separating pseudoglobulin.

With the pneumococcus antisera, it was found a number of times that Types V and VII showed considerable quantities of antibacterial substance in the supernatants. However, this was not always typical of these types, but more probably due to the previous history of the horses in these special cases because sera of these types from different horses caused no difficulty.

The usual methods of carrying out the agglutination and precipitation tests were used. When practicable, both were employed.

E. In this manipulation it was evidently impossible to avoid contamination. Using 0.2 per cent phenol and working in the cold, it was found that bacterial growth was practically negligible or very small and the formation of appreciable quantities of products of such growth avoided.

F. With some preparations, after solution, a gradual separation of protein substance occurred. This may have been fibrin or a conversion product of the globulin. Before use, this cloud or suspension was removed. As a rule, it contained no appreciable amount of active material.

G. The question of sterility was predominately important here. The comparatively large concentration of protein present in the final product and the occasional difficulty of filtering through a Berkefeld filter, necessitated special care for this part of the procedure. After various series of tests, it was decided to use 0.5 per cent phenol in all cases although recent experiments, as yet unpublished, by Miss Rosenstein and her coworkers in this laboratory have thrown considerable light on the efficacy of various disinfectants with different contaminants. Because of the possibility of the solutions becoming permanently cloudy on standing, a time limit of six months was placed on the clinical use of the materials. If, upon expiration of this time, the solutions were clear and showed no marked decrease in potency, they could be used directly. If, however, a cloud or suspension was present which did not dissolve on warming to  $37^{\circ} C.$ , the preparation was pooled, refiltered, rebottled, and retested for sterility and potency.

Potency tests have been described and discussed in detail at various times. Agglutinin and precipitin tests were carried out by Miss Cooper essentially as described in "d" and "e." Mouse protection tests were also carried out under the direction and supervision of Miss Cooper. The details of the method were given at various times by Felton,<sup>10, 11</sup> Park and Cooper,<sup>12, 13</sup> Falk, McGuire,

Valentine and Whitney,<sup>14</sup> and perhaps in most satisfactory form by Beard and Clapp.<sup>15</sup>

E1. The necessity of precipitating the total pseudoglobulin fraction by 50 per cent saturation with ammonium sulphate was obvious. Because of the possible inactivation by the salt, the precipitate was filtered on the day it was formed.

F1. The danger of contamination was present in this part of the procedure. The presence of the chloroform, care in closing the cellophane bag, and rapid working when the material was exposed, however, limited bacterial growth.

#### DISCUSSION

The procedure described is essentially that proposed by Banzhaf and Klein,<sup>4</sup> but with a number of modifications. The "acid protein" precipitation developed by Felton<sup>10, 11</sup> is one of the most important single steps in the method. If properly carried out, this step is fairly dependable in removing chill-producing substances from the preparations. Another important feature of the method is the prevention of bacterial growth and the formation of products of such growth which, if present, may well accompany the antibacterial substances in the various manipulations and produce undesirable clinical reactions.

The method as described was developed with antibacterial substances obtained by the use of the different types of pneumococcus. It has, however, been used in the refining of other antisera as will be outlined presently. The method has been in use for over two years at the Laboratories of the Department of Health with generally satisfactory results as far as the evidence available indicates. This does not mean that methods used in other laboratories such as various salt precipitations, or the alcohol method of Felton<sup>16</sup> are not equally satisfactory. The method described here is preferred by the writers because of its comparative simplicity.

The chill-producing and possibly other deleterious substances which are occasionally present offer the most direct problem for study. Felton's "acid protein" precipitation method is the most useful process available for eliminating such substances. With some sera one refinement is not sufficient to remove all of these substances, and the process must be repeated (including dialysis for several days, etc.). It is evident that where large amounts of antiserum, such as for pneumococcus Types I and II, are available, it is possible to carry out two, or even more, refinements with profit. With the other pneumococcus types where much less antiserum is available, the losses in refining comparatively small amounts, while in absolute quantity perhaps much the same as with large amounts, are so much greater in relative or percentage figures, that more than one refinement is inadvisable. This is perhaps the reason for the somewhat greater number of reactions observed clinically with the less common types of pneumococcus antiserum preparations, and not the fact that one process of refining is better than another, or that more information is available about certain types.

At the same time, much remains to be done in studying antisera for the various types. For example, as stated before, in carrying out this work, it was

found that certain preparations of Type V and Type VII pneumococcus antisera could not be refined by the simple dilution procedure, but required ammonium sulphate for precipitation. Similar materials from different horses could, however, be so refined. The cause for the different behavior is, at present, unknown. All that can be said is that the antibacterial substances were present in different fractions of the "pseudoglobulin" in these cases and that they existed in all probability in different fractions of the protein material in the sera of the horses. Such differences may well be due to repeated and long-continued inoculations and bleedings of the horses.

In connection with the method described in this paper, several facts may be pointed out. The conditions under which the experiments were performed were not satisfactory so far as the possibility of maintaining sterility was concerned. Even under these unavoidably adverse conditions, it was possible in most of the experiments to maintain sterility in the dialyzed solutions. The chill reactions of some of the final products may have been caused by the bacterial contaminations and growths which took place in some of the refinings. But the fact may be stated with some degree of emphasis that, in the opinion of the writers, it is not only possible but feasible to maintain sterility, or at worst to inhibit bacterial growth, under suitable conditions of working. It may be stated again that the method of refining and concentrating antisera here described is in no sense complete and final. It marks a step in that a method is presented, simple to carry out, and generally satisfactory although the preparations may sometimes require a second or even third reworking.

The questions of determining potencies and the clinical efficacies of the refined preparations do not come within the scope of this paper except in so far as the satisfactory attainment of certain standards is a necessary condition for the use of the method. The study of potency by mouse tests has been given by various workers a number of times. Where sufficiently virulent cultures were available, mouse units were used; otherwise agglutination and precipitation tests were resorted to as measures of the degree of concentration of the antibacterial substances in the refining process. Obviously the final volume of a preparation as compared to the initial volume controls the degree of the concentration but it may be said in general terms that the antibacterial substances were concentrated between five and ten times in the final preparation. The losses in active materials were difficult to estimate because of the inaccuracies inherent in the experimental method of determining potencies. In order to give a figure, which, however, cannot be considered as of a high order of accuracy, it may be said that, as a rule, between 50 and 100 per cent of the active material was recovered.

The description of the method referred to pneumococcus antisera. The same method, with practically no changes, was used with meningococcus antisera with equal success. It may also be used for additional antibacterial substances. Its possible application to other materials may be of interest. For instance, some experiments were carried out with scarlet fever antiserum which contained both antitoxin and antibacterial substances. Following dialysis and "acid protein" precipitation, the antibacterial substances were separated by

dilution at the most suitable hydrogen ion concentration followed by the precipitation of the antitoxin with ammonium sulphate to 50 per cent saturation. The clinical results with these two preparations (or more properly, protein fractions) were too few to warrant any statement, but the method is suggestive and may prove of interest and value.

The work described treats of the practical features of refining and concentrating antibacterial substances. The more purely scientific aspects of the problem have not been considered. There is, in fact, no evidence as to the nature of the active groupings or constituents of the anti substances. It would seem as if the time were ripe for a more intensive study of the chemical natures of these physiologically active materials. They, including both antitoxins and antibacterial substances, belong to the protein group of pseudoglobulins, which in general terms are less soluble than albumins and more soluble than euglobulins. This classification of the proteins is still arbitrary and based upon differences in solubility and not, as far as known, upon definite differences in chemical compositions and structures. The work of Svedberg and of the Reiners, to which reference has been made, brings out the arbitrary character of the classifications. The change in solubility of certain constituents on treatments in refining indicates this fact. For example, heating diphtheria and tetanus antisera with ammonium sulphate to 30 per cent saturation for an hour at 58° C. converts some of the inactive pseudoglobulin into insoluble protein.<sup>17, 18</sup> On standing (or on dialysis), precipitates may be formed with antibacterial products. These phenomena appear to involve the conversion of "pseudoglobulin" into "euglobulin." However, when the arbitrary nature of the classification is considered, to speak of the conversion of such constituents means nothing. Part of a protein fraction on simple treatment becomes insoluble (perhaps in a different nomenclature, denatured), and that is all that is known. Such simple changes taken in connection with the physiologic actions, however, may offer a promising field for study. Similarly, the precipitation of antibacterial substances, best at fairly definite hydrogen ion concentrations, these concentrations differing somewhat with different preparations, would also repay study. So far, chemical analyses have not succeeded in throwing light on any of these phenomena.

#### SUMMARY

The methods in use at the Bureau of Laboratories of the Department of Health of New York City for refining bacterial antisera are described. Various applications of these methods are discussed and some general theoretical relations given.

The writers wish to thank Messrs. Jerome Peltz, Eugene Cardone, Albert Glaubiger, and Edward Buxbaum for their aid in carrying out the experiments and in testing the details of the various procedures. Thanks are also due Miss Cooper, Miss Rosenstein, and their assistants for doing the many potency and sterility tests upon which the procedure was based.

## QUANTITATIVE DETERMINATION OF CHLORAL HYDRATE IN BLOOD AND URINE\*

MAX M. FRIEDMAN, B.A., AND FRANK A. CALDERONE, M.D., NEW YORK, N. Y.

GETTLER and Blume<sup>1</sup> have described a method based on the work of Cole<sup>2</sup> for the quantitative determination of small amounts of chloroform in tissues. The final step in the method is a pyridine color reaction with chloroform, known as the Fujiwara<sup>3</sup> color reaction. This color change is produced not only by chloroform but by all R-C-halogen<sub>3</sub> compounds.

In the course of some work we were doing on anesthetics, we found it necessary to determine the quantity of chloral hydrate in the blood and urine, and accordingly, after consultation with Dr. Gettler, we employed his method for this purpose. We met with difficulties, but these were overcome by certain modifications in the method. With these, we were able to determine quantitatively amounts of chloral in solutions containing as little as 0.001 per cent.

The procedure we employ for determining the amount of chloral hydrate

\*From the Department of Pharmacology, University and Bellevue Hospital Medical College, New York University.

Received for publication, December 6, 1933.

in blood is as follows: In a thin-walled test tube, about 200 by 20 mm. in size, is placed 2 c.c. of a 40 per cent NaOH solution, to which is added 1 c.c. pyridine (colorless) and then 4 c.c. blood filtrate prepared by the Folin-Wu method. In a similar tube is placed the NaOH and pyridine and 4 c.c. of a solution of chloral hydrate, for a standard. In our work the standard chloral hydrate solutions ranged from 1:20,000 to 1:100,000, the solution finally used for each determination being approximately that corresponding in chloral content to the blood filtrate. The two tubes are shaken simultaneously and equally and kept in a boiling water-bath for exactly one minute. They are then cooled by placing them in an ice bath for one minute. Six cubic centimeters of water is then added to each and the contents mixed by inversion. The contents are then filtered into colorimeter cups and readings made in the usual manner. The readings should be made within ten minutes from the time of heating, as the color changes on standing longer.

For determining the chloral in the urine the same procedure is followed but here the urinary pigments may interfere with the colorimetric reading. To obviate this instead of the final dilution with 6 c.c. of water, part of the water is replaced by an amount of urine corresponding to that taken for the chloral determination. Since the pyridine reaction does not occur in the cold, samples from the same urine are used in the water replacement. It is advisable that the concentration of the unknown should range between 0.01 and 0.05 mg. per c.c. If it is below 0.01 mg. it is necessary to add known quantities of chloral to obtain a satisfactory reading.

In checking the accuracy of the method described for blood chloral concentration, quantities of chloral ranging from 0.25 to 1 mg. were added to 3 c.c. of blood and the color read against standard aqueous solutions. The blood figures were within  $\pm 3$  per cent of the standard.

It should be pointed out that the method used seems to apply only to free chloral, or at most chloral which has been very little modified. When conjugated with glucuronic acid, chloral does not develop the pyridine color.

# A METHOD OF DAMPING THE KROGH TYPE OF SPIROMETER FOR STUDYING THE RESPIRATION OF RABBITS\*

CHARLES I. WRIGHT, PH.D., ANN ARBOR, MICH.

WHILE studying the effects of morphine and its derivatives on the respiration of rabbits the author had reason to believe that the Krogh spirometer being used did not follow accurately the respiratory volumes of the animals. The apparatus consisted of a 40-liter rebreathing tank connected directly to a

Fig. 1.—A record of the variations in amplitude of excursion of the undamped Krogh spirometer as described in the text. Upper tracing shows the variation at a volume of 25 c.c. and the rates (per minute) indicated. The lower tracing was made with a volume of 40 c.c. at the rates indicated.

Krogh spirometer (500 c.c. capacity) that recorded over two pulleys on a smoked kymograph paper. The float of the spirometer was made of phosphor bronze (0.038 cm. thick), and required a counterbalance weight of 80 gm. at a distance of 10 cm. from the axis of rotation. As a test of the ability of such a system to follow the respiratory volumes encountered, a 50 c.c. syringe was used to introduce known volumes of air into and out of the rebreathing tank. A kymograph record of the excursions of the spirometer showed at once that

This investigation was supported by a grant from the Committee on Drug Addiction of the National Research Council from funds provided by the Bureau of Social Hygiene, Inc., and the Rockefeller Foundation.

overshooting occurred at high rates (Fig. 1). The extent of this overshoot is shown by plotting the millimeter excursion of the spirometer against the rate at different volumes as given in Fig. 2. This graph shows an enormous overshoot starting at about 30 respirations per minute and a slight undershoot at rates below this point. It is obvious that with such a recording system no accurate

Fig. 2.—The variation in amplitude of excursion of the undamped Krogh spirometer with rate. Each curve represents a constant volume as indicated.

determination of respiratory volume can be made on rabbits since the respiratory rate of these animals varies between 30 and 80 per minute. Especially is this true if the animal is forced to breathe  $\text{CO}_2$ , which is frequently used as a respiratory stimulant.

A spirometer float of extremely thin (0.035 cm.) aluminum was made in an effort to reduce the mass, and thus the moment of inertia, sufficiently to allow

accurate recording at the rates involved. The overshoot was reduced, but by no means eliminated.

Finally an aluminum damping vane (diameter 5 cm.) was fastened, by

Fig. 3.—Diagram of the Krogh spirometer and the method of damping. The float, counterbalance arm, damping vane, and attachment are made of aluminum.

Fig. 4.—A record of the amplitude of excursion of the damped Krogh spirometer at the volumes and rates (per minute) indicated.

means of a hinged joint, to the counterbalance arm as shown in Fig. 3. This vane, immersed in oil as shown, effectively damped out all variations in the excursion of the spirometer at rates up to 100 per minute. The oil used is com-

mercial motor oil of a viscosity usually designated by S.A.E. 40. This oil critically damps the apparatus here described at room temperatures between 22° C. and 26° C.

A test of the pressures developed in the rebreathing tank showed that no significant change in pressure was introduced by the use of this damping vane.

Fig. 4 shows a record made by introducing volumes from 10 c.c. up to 50 c.c. at the rates indicated using the damped spirometer. As can be seen, there is no variation in depth with rate, and a plot of the excursion of the pointer on the spirometer against frequency at any one volume gives a straight line, parallel to the abscissa, up to frequencies of 100 or more.

## COMPARISON OF THE KOLMER-WASSERMANN, KAHN, AND ROSENTHAL TESTS FOR SYPHILIS\*

---

WITH SPECIAL REFERENCE TO THE USE OF THE LATTER IN THE PUBLIC  
HEALTH LABORATORY

---

ALBERT L. SCOTT, M.S., ROANOKE, VA.

---

IN RECENT years there has been a growing tendency on the part of syphilologists and laboratorians not to rely on a single test for the serologic diagnosis of syphilis. Some laboratories have replaced the time-honored Wassermann test with some simpler method, such as the Kahn test, but it is probably safe to say that most laboratories today use some modification of the Wassermann, checking the results by means of one or more of the flocculation tests. Of these the Kahn is probably the best known. The Kline test has more recently come to the fore as a simple microscopic test; it has been recommended by Kolmer<sup>1</sup> as being superior to the Kahn as a check test. In some laboratories it is routine to use both macroflocculation and microflocculation tests to check the Wassermann results. The purpose of this study was to determine the applicability of the newer Rosenthal microscopic test for use as a check method.

In 1929, Rosenthal<sup>2</sup> described a microflocculation method which was technically much simpler than the Kline test in that neither serum nor antigen was diluted, either before or after mixing, and tabulated the results obtained by testing 1,066 serums by the new method and by the Wassermann test. He found that the new test gave more clear-cut reactions with the weakly positive and doubtful Wassermann serums. Since it required only a small quantity of serum, it could also be used where only finger blood was available. In 1932, Tulipan and Director<sup>3</sup> reported the results of the Wassermann and Rosenthal tests on 1,067 serums, mostly syphilitic. They found that the two tests agreed in 986 instances, disagreed in 81. No disagreements were noted in individuals not clinically syphilitic. Of the 81 disagreements on clinically syphilitic cases, the Wassermann was positive and the Rosenthal negative on 17; the Wassermann

---

Received for publication, December 1, 1933.

was negative and the Rosenthal positive on 64. The majority of these disagreements occurred in tertiary cases and patients who had received treatment. These authors felt that the Rosenthal test tended to become positive earlier in the disease and to remain positive longer under treatment than the Wassermann. They recommended it for emergency uses, such as testing donors for transfusions, also to rule out negative serums before testing by more complicated methods.

In 1933, Burdon and Duggan<sup>4</sup> reported tests on 1,235 serums by the Kahn and Kline methods; on 400 of these they also used the Hinton, Meinicke clarification, Sachs-Georgi and a modified Rosenthal test. On the basis of their results they did not recommend the Meinicke or Sachs-Georgi methods, while they felt that the Hinton test was inherently limited in its practicability. Concerning the Rosenthal test they stated: "Our brief experience with the Rosenthal test has led us to believe that it is a method of real value as a supplementary procedure and that it would be especially useful in those laboratories where the Kahn test is done routinely, since the Kahn alcoholic extract, the only necessary reagent except a 2 per cent cholesterol in acetone solution, would be on hand at all times. The method is simple, rapid and economical. The results show that it is practically as sensitive as the Kline test, and no false positives were recorded. The reactions, however, were by no means as clear-cut as those of the Kline method, and in tests with normal serums the emulsion may develop a diffuse granularity which one must learn by experience to disregard." The modification of technic described by these authors will be detailed later.

#### TECHNIC

As devised by Rosenthal, the test was conducted as follows: Capillary pipettes were drawn from glass tubing, being kept together to form matched pairs. With one pipette 4 drops of inactivated serum were blown into the depression in a hollow-ground slide; with the other one drop of the antigen was added to the serum. The two were then mixed with a glass rod and, after a short time, examined under the low power objective. This method was used without significant change by Tulipan and Director. For the present study the modification of Burdon and Duggan was used. By this method the test is carried out as follows:

Glassware: Slides, 3 in. by 2 in. with twelve paraffin rings are substituted for the hollow-ground slides. The paraffin rings are made according to the technic for the Kline test.<sup>5</sup> I have found that a piece of 22 or 24 gauge nichrome wire makes a more sturdy loop than the two turns of iron wire suggested by Kline. Slides with twelve depressions ground in would be a timesaver where large numbers of tests are to be run, but for most laboratories the cost would probably be prohibitive. One eastern supply house quoted such slides at approximately \$2.00, each.

Pipettes: Those used for the Wassermann or Kahn tests may be employed.

Antigen: No. I. Kahn standard alcoholic beef heart extract (not cholesterinized).

No. II. Two per cent solution of cholesterol in chemically pure acetone.

The stock solutions are kept at room temperature and mixed in equal parts for use. The mixed antigen keeps well for from one to two weeks. Rosenthal tinted the antigen with methylene blue, but this is not essential to ease in reading.

**Method of Test:** Five-hundredths cubic centimeters of undiluted inactivated serum is pipetted into the paraffin ring. More than twelve tests should not be set up at one time. A drop of the antigen mixture is then allowed to fall on the surface of each serum from a pipette delivering about 0.015 c.c. per drop. I have found that a Schick test (27 gauge) needle on a small syringe makes a very satisfactory substitute for the capillary pipette, delivering approximately the correct amount of antigen. The annoyance of having the tip of the pipette become broken, possibly in the midst of a series of tests, is also obviated. Magath<sup>6</sup> suggested sealing a needle into a glass tube for use as an antigen pipette for the Kline test; this expedient could also probably be successfully used in the Rosenthal method. The time of addition of antigen to the serums is noted, and each preparation stirred with a separate toothpick. They are then examined under the low power objective, focusing on the surface of the drop. A preliminary observation is made of the character of the granular field; the final reading is made within from five to eight minutes, never more than ten, from the time the antigen was added. A negative reaction appears as a granular suspension, evenly distributed; slight clumping is noted as doubtful; well-defined clumps as positive, and large clumps in a clear field as strongly positive. A clear distinction between 2, 3, and 4 plus cannot be made.

**Wassermann and Kahn Tests:** Kolmer's three-tube qualitative modification of the Wassermann test<sup>7</sup> was used as the basic test in the examination of all serums, and agreement with it was considered the criterion of efficiency. The Kahn test was performed in accordance with the directions given by Todd and Sanford,<sup>8</sup> using antigens obtained from the Difco Laboratories. Kahn tests on the first 707 serums in the study were made with the "standard" antigen, the remaining 483 were tested with the "sensitized" antigen.

**Interpretation of Results:** The majority of the blood specimens examined in this laboratory come from the Municipal Venereal Disease Clinic, and of these the largest percentage is from colored patients. Cases of anticomplementary Kolmers accompanied by agreement of the Kahn and Rosenthal tests were considered as absolute agreement. In case of discrepancy in the two latter tests, additional specimens were taken, if necessary after a provocative injection of neoarsphenamine, until either positive or negative Kolmer reactions were obtained. However, these cases of anticomplementary Wassermanns with disagreement in the two check tests are listed as separate classifications in Table I, in which the various combinations of results are tabulated. A doubtful Rosenthal reaction with a negative Kolmer and Kahn test was considered as negative, except in treated cases, but with a positive Kolmer and Kahn reaction it was considered positive. In treated cases a positive or doubtful Rosenthal, even with a negative Kolmer and Kahn test, was considered as indicating the necessity for further treatment.

## RESULTS OF TESTS

In this series of tests we have examined 1,185 specimens of blood and 5 of spinal fluid. Four of the latter were negative by all three tests, the fifth gave a 4 plus Kolmer, negative Kahn and doubtful Rosenthal. The results with the Rosenthal test as applied to spinal fluid are thus seen to be rather inconclusive, and further study along this line would be desirable; however, these five specimens are included in Table I, with the results on the 1,185 blood specimens. There were 836 specimens for diagnosis; these are designated "New" in the table. There were 290 for the result of treatment, and 64 were unclassified in this respect. Some of the patients classified as new were known to have received

treatment from one to twenty years previously, but their blood tests were not made as a check on such treatment, but rather for diagnostic purposes.

The first division of Table I records the tests which may be considered as absolute agreement; the second division those in which disagreements occurred

among the three methods; and the third division those specimens on which one or two of the tests were not done, due usually to an insufficient amount of serum, breakage of tubes, etc.

Consideration of Tables I and II shows that the Rosenthal test is apparently more sensitive than either of the other two, especially in the cases of patients who have received treatment. It will also be noted that the greatest number of discrepancies falls in the class of treated cases. These findings are in accord with those obtained by Tulipan and Director. Contrary to these authors and also to Burdon and Duggan, Table I shows a number of examples of what must have been false positives although several of the serums may have been from early cases of syphilis or from patients who had previously received treatment.

Of the 180 disagreements noted in the second division of Table I, 147 showed negative Kahn tests with positives by either one or both of the other methods. Of this group, 94 were included in the 707 specimens examined with the standard antigen, while 53 were part of the 483 tests made with the sensitized antigen. This gives percentages of 13.2 and 10.9, respectively. This reduced sensitivity of the standard antigen was also remarked by Burdon and Duggan.

From the standpoint of practicability, it is desirable to know what percentage of agreement may be expected from the tests under consideration, or from various combinations of them. These figures are tabulated in Tables II and III.

TABLE III

| IN AGREEMENT               | NUMBER | PERCENTAGE OF TOTAL |
|----------------------------|--------|---------------------|
| Kolmer, Kahn and Rosenthal | 977    | 82.1                |

## SUMMARY AND CONCLUSIONS

Results are presented covering the examinations on 1,185 specimens of blood serum and 5 spinal fluids by the Kolmer-Wassermann, Kahn, and Rosenthal tests. Comparisons are tabulated, giving the percentages of agreement between the various combinations of tests. On the basis of these results, we may conclude that the Rosenthal test is an accurate, simple, and economical method, agreeing well with the Wassermann and Kahn tests. On these grounds it can be recommended as a check test, or as a preliminary test, to be checked later by other methods. It is especially applicable to the public health laboratory, where the short time requirement (twelve tests may be set up and read in ten minutes) will commend it to most laboratorians. The fact that it may be performed with finger blood and in such a short time makes it a valuable procedure for use in the hospital laboratory as an emergency method, such as for testing donors for transfusions. In this connection it is to be remembered that the antigen may be kept on hand and a single test set up without any bother of making dilutions or waste from preparing a quantity of reagent. It may also

be found useful in the routine suggested by Tulipan and Director, that of testing first by some simple method to rule out the frank negatives, then testing positive and doubtful serums by other methods to confirm or disprove the preliminary findings.

As with any study of this type, the results obtained give rise to other interesting problems which must be passed up in this laboratory. The question of whether the positive Rosenthals with negative Kolmer and Kahn reactions in new patients are really false positives or whether they are incipient syphilis or beginning cerebrospinal syphilis, could be solved by the aid of a well-organized social service follow-up work. It would also be interesting to tabulate such a series as this one on the basis of the part of the body involved, that is, visceral, cerebrospinal, bone, etc. This could best be done in a large hospital center.

The author wishes to express his appreciation to the following men for their criticism of the manuscript during its preparation: Dr. G. D. Johnson, Dr. H. H. Wescott, Dr. K. D. Graves, Dr. W. F. Manley, Dr. W. C. Stephenson, Jr., and Dr. K. T. Redfield.

## AN AUTOMATIC-FILLING INK RECORDING SYSTEM AND PERMANENT TYPE WATER MANOMETER\*

---

J. P. QUIGLEY, PH.D., CLEVELAND, OHIO

---

**A**N INK recording system on apparatus such as the water or mercury manometer, signal magnet, etc., has distinct advantages over the ordinary smoked paper recording method. The apparatus indicated in Fig. 1 is sturdy, durable, simple, and of light weight. The ink recorder and the permanent type water manometer (Fig. 2) have been continuously used with satisfaction in balloon studies of gastrointestinal motility for the past two years. A manometer having the dimensions indicated is satisfactory for many purposes, and manom-

eters of this type, which are exact duplicates or definite variations, can be made to subserve special purposes. Difficulties related to air leaks are largely eliminated, and the necessity of making replacements is decreased by the avoidance of most of the rubber tubing employed on ordinary manometers.

Fig. 2.—Permanent type water manometer. Glass tube *A* and brass tube *B* set into brass blocks, *G* and *H*; *C*, tube of soft copper or lead (reaches to balloon tube inserted in animal); *D*, brass tube sweated into *H* and fitted at outer end with short length of rubber tube and clamp (employed in adjusting pressure within system); *E*, thin-walled glass float sealed to float rod of flexible wire and light weight capillary tubing; *F*, brass rod sweated into *G* (used with *D* to support manometer).

# DEPARTMENT OF REVIEWS AND ABSTRACTS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

UNDULANT FEVER, "Brucellin," a Possible Specific for, Huddleson, I. F., and Johnson, H. W. *Am. J. Trop. Med.* 13: 485, 1933.

The authors comment upon the various pitfalls surrounding the accurate diagnosis of *Brucella* infection, emphasizing the uncertainty of blood cultures, especially in infections of the suis or abortus varieties, and the difficulties of accurate interpretation of agglutination titers.

They have developed what they consider a satisfactory procedure for the detection of active *Brucella* infection utilizing both an allergic skin reaction and a determination of the opsonophagocytic power of the patient's blood.

These procedures are carried out as follows:

*Brucella Allergic Skin Test.*—The test solution is a soluble nucleoprotein fraction made from the three species of *Brucella* in 1:1,000 dilution in slightly alkaline physiologic saline.

The test is made by injecting about 0.1 c.c. of the fluid intracutaneously in the upper anterior surface of the forearm using a 26 gauge needle. The size of the local reaction, which is characterized by a circumscribed erythema and edema, may vary from 1 to 2 inches in diameter and appears within from four to forty-eight hours after injection. It may persist for from forty-eight to ninety-six hours. There is invariably no necrosis or sloughing of the tissue at the point of the local reaction. In the infected, the local reaction may be accompanied by a more marked manifestation of symptoms. Those that are hypersensitive will show a severe systemic reaction along with the local reaction. Those that have not been sensitized to *Brucella* and who are probably susceptible to infection show no local or systemic reaction. One often sees in certain individuals an erythema, about  $\frac{1}{2}$  to 1 inch in diameter with no edema around the point of the injection. It has the appearance of a nonspecific reaction.

*Determination of Opsonophagocytic Power of Blood.*—(See abstract published in June issue, page 1024: Huddleson, Johnson, and Hamann, "A Study of the Opsonocytophagic Power of the Blood and Allergic Skin Reaction in *Brucella* Infection.") This is a modification of the Leishman-Veitch technic and consists in mixing equal quantities of a citrated (0.8 per cent sodium citrate) fresh blood and a heavy bacterial suspension of living organisms in a small Wassermann tube, incubating at 37° C. for thirty minutes, and subsequently making spreads and staining with Hastings' stain. The addition of a definite amount of sodium citrate prevents clotting of the blood and inhibits the action of *Brucella* opsonins which are present in the serum of many normal individuals.

This paper is particularly concerned with a report of the therapeutic results obtained with "Brucellin," a product developed by the authors which may possibly prove a specific for the treatment of undulant fever.

This agent is prepared by growing each of the three species of *Brucella* in separate flasks of beef liver infusion broth, adjusted to a  $P_H$  of 6.6, for sixty days at 37° C. The inoculated flasks are shaken vigorously at weekly intervals. At the end of the stated growing period, each flask is examined bacteriologically and, if found contaminated, is discarded. The broth is clarified by centrifugation at a speed of 3,000 r.p.m. for four hours. The clear liquid is decanted and adjusted to a  $P_H$  of 7 with N/1 HCl. The product from each of the three species is now pooled and filtered twice through sterile Berkefeld N filters. The filtered liquid is transferred to sterile flasks or tubes and incubated for five days at 37° C. to determine sterility. It is standardized and transferred to sterile 1 c.c. vials or stored in larger containers until ready for use. The duration of its potency has not been fully determined.

When a certain diagnosis of undulant fever has been made, an intradermal injection of about 0.05 to 0.1 c.c. of "Brucellin" should first be given to determine the sensitiveness of the patient to this material. If no marked systemic reaction is elicited within forty-eight hours after the intradermal injection, one may give 1 c.c. intramuscularly. This dose should be repeated at intervals of three days until four injections are given. The intramuscular injections usually cause a local reaction and the temperature of the patient to rise to 104 or 105° F. About one to three hours after the temperature reaches its highest point, it begins to fall by steps or may rapidly drop to near normal. There is as a rule an increase in the severity of the symptoms, such as headache, muscular pains, chills, and sweating. The increase in the severity of the symptoms usually does not persist for more than twenty-four hours. The temperatures of patients treated within the fourth week after the onset tend to return to normal or subnormal after the second injection.

If the systemic reaction from the intradermal injection is quite severe, it is advisable to start the intramuscular injections with 0.1 or 0.2 c.c. If there is no severe systemic reaction following the intramuscular injection of the smaller amount, the succeeding dose at the end of the three days may be doubled. Each dose thereafter may be doubled, providing the systemic reaction is not severe, until 1 c.c. is reached. Three successive 1 c.c. injections may then be given. Certain individuals show very little systemic reaction to 1 c.c. amounts of "Brucellin." Such patients do not respond to treatment until after the dose is increased to 3 or 5 c.c. amounts.

In case children are treated with "Brucellin," the beginning dose should be 0.2 c.c. If the reaction which follows is not severe, each succeeding dose at three-day intervals may be doubled until 1 c.c. is reached. Three successive 1 c.c. injections may then be given.

The ambulatory or chronic type of case of long standing does not respond as readily to four 1 c.c. injections of "Brucellin" as those of three months' duration and less. It may be necessary to gradually increase the dose to 5 c.c. by 1 c.c. steps in order to effect recovery in cases of long standing. Several cases, however, of from eight to twelve months' duration have responded very readily to four injections of "Brucellin." The response to treatment made by infected infants and children, including those in which the disease has assumed the meningeal form, is very striking.

One should not try to avoid systemic reactions from injections of this material. It is necessary to produce two or three systemic reactions in order to bring about recovery.

If it is possible, one should determine the opsonocytaphagic activity of whole citrated blood for *Brucella* after the fourth injection as it has been observed that the phagocytic activity of the blood for *Brucella* is one of the surest criteria of complete recovery from infection. In the absence of such a test one must be guided in determining recovery by the disappearance of the clinical manifestations of the disease, by the appearance of a subnormal temperature, change in mental attitude of the patient and marked increase in the appetite.

Because of the danger of severe systemic reactions as a result of sensitization, it is essential that "Brucellin" be used only for active cases and never injected into a recovered patient. The necessity for accurate distinction between a recovered patient—recognized by the presence of agglutinins, for example—and an active infection is obvious and cannot be overemphasized.

"Brucellin" has been used in the treatment of 80 cases with excellent results.

#### SWIMMING POOLS, Some Factors Involved in the Use of Chloramines for the Disinfection of, Fletcher, A. H., and Link, E. C. *Am. J. Pub. Health* 23: 1255, 1933.

The decided advantage in the use of chloramines for disinfection of swimming pools having a slow rate of recirculation, poor spacing of inlets, hand application of chlorine, or those operated as fill-and-draw pools, and especially when the pool is out of doors, has prompted its use for another season.

The use of chloramines instead of chlorine alone requires certain extra tests and control to guard against its limitations. Some of these are: (a) the requirement of higher

residuals, that is from 0.7 to 1 p.p.m.; (b) the control of the ratio of ammonia to chlorine and of the free ammonia content in the water; (c) the control of the  $P_H$  of the water routinely; and (d) the collection of all samples in sodium thiosulphate-treated bottles.

The duplicate series of tests on ordinarily collected samples and dechlorinated collected samples showed a lag in the killing power of chloramines over the chlorine on *B. coli*.

A moderate excess of sodium thiosulphate when used as an antichlor was found to have no disinfecting effect.

Copper sulphate, if added every second night after closing at a dosage rate of 5 lb. to each 100,000 gal. of water, definitely and completely controlled algae or slime growth at any pool where it occurred in Memphis.

**STREPTOCOCCI, Hemolytic Properties of the Mastitis, Hansen, P. A., Hucker, G. J., and Snyder, M. A. Am. J. Pub. Health 23: 1262, 1933.**

Of 91 authentic strains of *S. mastitidis* being carried in various laboratories as typical streptococci associated with mastitis 50 were of the alpha and 41 of the alpha prime hemolytic types.

The streptococcus commonly associated with chronic or subclinical mastitis always produces the alpha or alpha prime type of hemolysis on blood agar, bordering on a slight beta hemolysis. Strong beta hemolytic strains were not found among the cultures. Two strains of streptococci from mastitis were beta hemolytic, but they were found by cultural studies to be different from the type generally found associated with mastitis.

A careful study of the authentic mastitis streptococci isolated from chronic cases reported to be beta hemolytic were found to be of the alpha prime type. This distinction is apparent when deep colonies are examined by a stereoscopic binocular microscope.

Blood from sheep, ox, and horse was used with similar results. The type of blood did not appear to affect the type of hemolysis produced on blood plates.

**PREGNANCY, The Sex Determination Test of Dorn and Sugarman, Curphey, T. J., and Romer, A. S. J. A. M. A. 101: 1680, 1933.**

From their experimental study the authors conclude: It is evident that there is no constant agreement whereby the changes excited in the testicle of the rabbit can be used to predict the sex of the unborn child.

Using a pure bred strain of New Zealand white rabbits, they were unable to confirm the observations of Dorn and Sugarman as to the prediction of sex in the unborn child.

The age of the experimental animal and the anatomic location of the testicle at the time of intravenous injection of urine of pregnancy apparently plays no part in the matter of testicular stimulation.

There is present in the urine of pregnant women a so-called spermatogenic factor unassociated with the sex of the unborn child.

The need exists for a further investigation as to a possible relationship between this spermatogenic factor and toxemic states of pregnancy.

**TUBERCULOSIS, Effect of Vaccination With BCG on Children From Tuberculous Families, Park, W. H., Kereszturi, C., and Mishulow, L. J. A. M. A. 101: 1619, 1933.**

From the results of these investigations it appears that B.C.G. is so attenuated that even under the most favorable conditions of artificial cultivation it is difficult to increase its virulence to any degree. During the past five years, the virulence of the B.C.G. vaccine was tested on 165 rabbits and 194 guinea pigs but no evidence was found of any increase in virulence. Twenty cultures of acid-fast bacilli that were recovered from the cold abscesses of seventeen children after from one to six months' stay in the body showed no increase of virulence, but remained like the B.C.G. in colony morphology and were nonvirulent for rabbits and guinea pigs.

One culture was recovered from the mesentery of an orally vaccinated child six weeks after vaccination. This culture showed no increased virulence and culturally was typically like B. C. G.

The pathologic material that was obtained from children who were vaccinated with B. C. G. and died of other infections showed no evidence that B. C. G. tended to increase in virulence during its residence in the human body.

On the basis of their limited experience and on the basis of publications of others, the authors do not think that slight primary tuberculous infection acquired by natural infection or produced by vaccination diminishes resistance against future superinfections by tuberculosis.

Children of tuberculous families vaccinated orally with B. C. G. show lower mortality from tuberculosis than corresponding controls.

None of the parenterally vaccinated children died of tuberculosis, whereas the children who were not vaccinated and were similarly exposed showed about 3 per cent mortality from tuberculosis. There was no appreciable difference in the mortality of the controls who had negative roentgen findings in the chest when they were first seen, whether they had negative or positive initial tuberculin tests.

Tuberculin tests performed on 148 nonvaccinated children followed up since birth and on 205 children orally vaccinated with B. C. G. before their tenth day showed, during the first two years of life, from 20 to 40 per cent more positive Mantoux tests among the latter cases. The allergy produced by B. C. G. apparently does not usually last for more than two or three years.

Comparatively few of the control children developed positive reactions to tuberculin, even when they were more or less exposed to open tuberculosis, i.e., 20 per cent in the first year and 50 per cent up to the fourth year.

If repeated tuberculin tests are performed through the years, a small percentage of the slightly or moderately positive reactions become negative.

**NEPHRITIS, Types of and Their Management, Christian, H. A. J. A. M. A. 102: 169, 1934.**

The present study of lipoid nephrosis and the so-called "nephrotic syndrome" suggests that lipoid nephrosis, in adults at least, is a form of Bright's disease.

The frequent association of lipoid nephrosis with definite glomerular nephritis, the fact that cases of clinically pure lipoid nephrosis may terminate in uremia from the end-stages of glomerular nephritis, and the fact that not a single case typical of lipoid nephrosis in an adult has come to postmortem examination at the Mayo Clinic suggest that at least most cases of lipoid nephrosis represent a stage in, or an unusual type of, glomerular nephritis. If other cases occur, they are extremely rare.

The relatively high percentage of patients who have been cured of lipoid nephrosis, or who have shown marked and prolonged improvement, and the relatively slight evidence of glomerular nephritis in most instances at postmortem examination, even among patients who have given clinical evidence of glomerular nephritis, justify the grouping of these patients clinically in a separate group from that of ordinary glomerular nephritis. As long as the term lipoid nephrosis has been so uniformly accepted there seems to be no good reason for changing it.

**SERUM PROTEINS, In Diseases not Primarily Affecting the Cardiovascular System or Kidneys, Peters, J. P., and Eisenman, A. J. Am. J. M. Sc. 186: 808, 1933.**

From an analysis of 109 total protein determinations from 52 individuals and of 50 protein fractions from 34 individuals, the following limits of normal variation have been defined: for total protein, from 6 to 8 per cent; albumin, from 4 to 5.5 per cent; globulin, from 1.4 to 3 per cent. Globulin in excess of 2.5 per cent was found only in the winter months and may represent effects of respiratory infections which are so prevalent in this climate at that season.

Total proteins have been determined 542 times in 374 patients suffering from various diseases which do not affect directly the cardiovascular or renal systems, and in 215 of these subjects 332 determinations of protein fraction have been made. The data have been analyzed from various points of view and the following conclusions have been drawn.

The relation between edema and the estimated protein osmotic pressure is in keeping with the theory of Starling.

Reductions of albumin can be connected almost invariably with malnutrition.

Increases of globulin are found with infections, especially suppurative processes and ulcerative tuberculosis or syphilis; in connection with certain tumors, particularly myelomata, and in cirrhosis of the liver.

The study has thrown no light on the sites of production of the two protein factors.

**TRICHINIASIS, The Use of an Intradermal Test in the Diagnosis of, McCoy, O. R., Miller, J. J., Jr., and Friedlander, R. D. J. Immunol. 24: 1, 1933.**

Of 36 persons ill with trichiniasis (i.e., two to six weeks after infection) 25 (70 per cent) gave positive immediate skin reactions following intradermal injection with 0.1 c.c. of a 1:10,000 dilution (in terms of dry weight of powder) of a saline extract of *Trichinella spiralis* larvae. An additional 8 reacted to a 1:500 dilution of the antigen making a total of 33, or 92 per cent positive.

Of 39 persons tested from three to twenty-two months after infection, 19 (49 per cent) reacted to the 1:10,000 dilution and an additional 12 were positive to a 1:500 dilution, a total of 31 or 80 per cent positive.

Of 13 persons ill from three and one-half to seven and one-half years prior to the test, 3 (23 per cent) were positive to the 1:10,000 dilution, and 5 more reacted to the 1:500 dilution, a total of 8 or 62 per cent positive.

One hundred and four control persons from Rochester, N. Y., showed an incidence of 9 per cent positive with the 1:10,000 dilution and a total of 18 per cent positive with both the 1:10,000 and 1:500 dilutions. Forty-seven control persons from San Francisco, Calif., showed an incidence of only 4 per cent positive to the 1:10,000 antigen and 6.5 per cent positive with both the 1:10,000 and 1:500 dilutions.

Ninety-two persons from southern Louisiana infected with *Trichuris trichiura* showed an incidence of 18 per cent positive with the 1:10,000 dilution and a total of 62 per cent with both the 1:10,000 and 1:500 dilutions.

From the data given in the present paper it appears fairly well established that about 90 per cent of persons ill with trichiniasis will give a positive skin test to the trichinella antigen provided the disease is sufficiently established. This period is apparently between two and three weeks after infection although in some cases a positive skin test may not appear until the fourth week.

The first consideration which complicates the interpretation of a positive trichinella skin test is the possibility that a previous light infection which has nothing to do with the present illness is responsible for the sensitization. This possibility is somewhat reduced by the fact that there seems to be a tendency to lose sensitivity over a period of years following infection.

Another consideration which must be thought of in the interpretation of a positive trichinella skin test is the possibility that the reaction is a Group I due to infection with *Trichuris trichiura*. The data show that most of these group reactions occurred with the 1:500 dilution of the antigen, but that a few probably occurred also with the 1:10,000 dilution. From the series of control tests performed, the authors are of the opinion that worm infections, other than trichuris, allergic disturbances, or other ordinary diseases are not an appreciable factor in causing group reactions to the 1:10,000 dilution of the trichinella antigen. It is possible, however, that in isolated instances group reactions may occur. In such cases it would probably be advisable to perform control tests with other proteins.

From a practical standpoint the trichinella skin test cannot be considered a certain diagnostic test. It appears that a negative test will probably prove more useful in ruling

out the diagnosis of trichiniasis than a positive one in establishing it. A positive test, however, definitely strengthens the evidence for the diagnosis and may justify further search for the parasite. Positive tests obtained with antigen dilutions of 1:10,000 or higher are of more definite diagnostic value than those obtained with lower dilutions. A year's experience in using the skin test in hospitals where trichiniasis not infrequently occurs leads the present authors to the conclusion that it may be a valuable aid in the diagnosis of the disease.

**TRICHINOSIS, A New Jersey Outbreak of, With Report of a Case Complicated by Femoral Thrombosis, Kilduffe, R. A., Barbash, S., and Merendino, A. G.** *Am. J. M. Sc.* 186: 794, 1933.

A case of trichinosis complicated by femoral thrombosis is reported together with the particulars of an outbreak arising from the ingestion of homemade sausage and involving 43 persons.

**TRICHINOSIS, Bachman Intradermal Test in Human, Kilduffe, R. A.** *Am. J. M. Sc.* 186: 802, 1933.

The results of the application of Bachman's skin test applied to 33 individuals exposed to trichinosis are reported and analyzed, from this analysis the author concluded that in the study of human trichinosis:

1. The demonstration of eosinophilia is not only technically simpler than the demonstration of the skin test, but always feasible, whereas the skin test, requiring an antigen difficult to prepare, is feasible only when the antigen is available.

2. In point of delicacy and constancy of appearance eosinophilia serves as a reliable index of trichinosis in the human being.

3. The Bachman skin test in the study of human trichinosis presents no practical advantages over the demonstration of eosinophilia.

**NEUTROPENIA, Benign and Malignant, Beck, R. C.** *Arch. Int. Med.* 52: 239, 1933.

Because of its comprehensive survey of the subject this paper should be read in the original, as its character precludes a satisfactory abstract. The summary following indicates the completeness of this review, which is followed by a report of 4 cases.

The subject of benign and malignant neutropenia has been covered, and this information has been compiled in more or less textbook fashion.

Many names have been proposed for this disease entity, benign and malignant neutropenia seeming to be the most appropriate.

The two groups, benign neutropenia and malignant neutropenia, have been further subdivided into primary and secondary types, depending on the etiology. A classification is based on this method of distinction and on the clinical course, which tends to give a mental picture of the types that make up this disease.

A review of the physiology of granulopoiesis is given, since the accuracy in interpreting the blood picture in primary benign and malignant neutropenia is dependent on an understanding of the underlying mechanism of granulopoiesis.

A review of the theories of pathogenesis of benign and malignant neutropenia is covered, and a theory is formulated based on the underlying pathology and physiology of granulopoiesis. It is suggested that in each case of neutropenia it would be advisable to determine the etiology and underlying changes in the bone marrow. Biopsies on specimens of bone marrow in all cases before treatment is given would prove or disprove the theory of an endogenous disturbance of chemotactic and maturation factors for granulocytes as being the cause of this disease.

The pathology of the characteristic lesions has been covered, and complete laboratory data given.

Symptoms, diagnosis, differential diagnosis, and prognosis have been discussed.

A section is devoted to a theoretical consideration of the treatment for this disease, as well as a review of all forms of treatment to be found in the literature. The rationale of these treatments, when possible, has been discussed. The theory is advanced that a specific treatment for malignant neutropenia involves an investigation of the chemical maturation factors which determine the granulocytes.

**SILICOSIS, The Pathology of So-Called Acute, Gardner, L. U.** *Am. J. Pub. Health* 23: 1240, 1933.

A histologic study of 15 cases of so-called "acute" silicosis has been reported. This was based upon examination of the lung tissues of 9 tunnel workers exposed for from nine to thirteen months, 3 sand blasters, for twelve to seventeen months, and 3 sand pulverizers on whom satisfactory histories of exposure were not obtained. Chemical analysis demonstrated that their lungs contained as much silica as those of South African gold miners employed for long periods. Their alleged occupational exposures did not exceed seventeen months, a contention which is supported by the early age of the group as a whole. These men died of infection from nine to twenty-one months after ceasing work. In 11 of them the infection was considered to be definitely tuberculous, and in 2 others it was probably so. The other 2 had unresolved pneumonias. All but 1 of them, a tunnel man for thirteen months, presented microscopic lesions characteristic of silicosis, but in no case was the disease sufficiently far advanced to be diagnosed on gross examination of the fixed tissues. The character and distribution of the changes did not resemble that usually seen in silicosis among miners and others who have died after prolonged exposures. This silicosis was characterized: (1) by masses of small nodules embedded in broad sheets of fibrous tissue surrounding the pulmonary lymphatics instead of isolated conglomerate nodules along the trunks and in the pulmonary parenchyma; (2) by a generalized fibrous thickening of the alveolar walls, which is generally considered to be a late manifestation; and (3) by the absence or only slight involvement of the mediastinal lymph nodes which are usually replaced by fibrosis before extensive changes appear in the lung. These differences were interpreted as due to the inhalation of such excessive amounts of fine dust that little of it could be eliminated by the lymphatics. In most cases the tuberculous complication was so acute that it probably developed after the reaction to the dust was well established, and thus failed to influence the picture greatly.

The acuteness of the infection was explained by the fact that the majority of the men were young negroes with presumably little immunity to tuberculosis. Although there is histologic evidence of silicosis, atypical in character, it seems doubtful whether there is justification for describing the process as "acute." At least this should only be done after serial roentgenograms together with postmortem examinations have demonstrated the outcome of the allegedly heavy exposures to silica. The difficulty in properly evaluating the element of infection in the tissues suggests the need for caution in the interpretation of roentgenograms.

**SILICOSIS, Silica Content of Lungs of a Group of Tunnel Workers, Smith, C. S., and Wikoff, H.** *Am. J. Pub. Health* 23: 1250, 1933.

The lungs of 9 workmen engaged in the same tunnel project have been analyzed.

There is a striking correlation between the per cent  $\text{SiO}_2$  in the dried lung substance and the severity of silicosis as determined histologically.

The per cent  $\text{SiO}_2$  in the dried lung substance is a better criterion of the intensity of silicosis than is the per cent of silica in the total ash.

**BLOOD, Is Halometry Reliable? Chaudhuri, H. P.** *Indian J. M. Research* 21: 315, 1933.

From an extensive statistical and comparative study, it is concluded that the halometric determination of the size of erythrocytes furnishes reliable data.

### An Outline of Immunity\*

AS THE author pertinently remarks in his Preface, there is probably no subject in a less satisfactory position than that labeled "Immunity." "A hybrid creature, not quite sure of its true affiliations; wandering uneasily between the Departments of Pathology, Bacteriology, and Hygiene; at times attempting to set up a house all by itself; a vigorous infant among the sciences, just rising fifty years, like most young and vigorous things, it is a little uncertain in its movements, a little confused in its mind, and at times more than a little incoherent in its speech."

Few who are familiar with the many, and at times not a little startling developments in the field of immunity within comparatively recent times, will deny the aptness of Professor Topley's characterization of his subject. That he has been able to present as clear and as comprehensive a survey of so complicated a subject as he has given in the present volume is a matter upon which the medical profession may well congratulate him and itself.

This is a book which should prove of inestimable value not only to the student and laboratory worker, but to the physician at large who, obliged almost daily to utilize the phenomena of immunity in the treatment and prophylaxis of disease, is obliged also to do so often without clear apprehension of the principles involved and their practical application.

In the twenty-one chapters of this volume the present concepts of immunity are reviewed, summarized, and correlated in a comprehensive and authoritative way. The book, far from being abstruse and concerned with hypothesis, is eminently practical in its outlook and consistently concerned with the practical aspects of immunity as related to the prophylaxis and treatment of disease.

An excellent feature is the succinct yet clear summary at the end of each chapter which, together with the excellent index, renders the contents of the volume readily accessible.

This book may be highly recommended as serving a useful purpose and as presenting a highly practical survey of an important and complicated subject.

---

### Coccidia and Coccidiosis†

COCCIDIA, in their relation to disease in animals and man, have attracted attention in many and diverse fields as witnessed by the numerous papers concerning coccidiosis which have appeared in journals of various types.

This field, however, is a highly specialized one, the literature of which is so widely scattered as to be almost inaccessible to even the specialist with good library facilities.

This monograph, therefore, serves a most useful purpose in bringing together under one cover descriptions and illustrations of the different coccidia found in various hosts and presents, in addition, the results of investigations in the study of "host-parasite-relationships."

---

\*An Outline of Immunity. By W. W. C. Topley, Professor of Bacteriology and Immunology, University of London. Cloth, pp. 415, 37 figures, 63 tables. William Wood & Co., Baltimore, Md.

†Coccidia and Coccidiosis of Domesticated, Game, and Laboratory Animals, and of Man. By Elery R. Becker, D.Sc., Associate Professor of Protozoology, Iowa State College. Cloth, pp. 147, 25 figures. Collegiate Press, Ames, Iowa.

Throughout the book much attention has been paid to discussions of those phases of coccidiosis which have been the subject of misconception in the past, such as host-specificity, the nature of species, the relationship to disease, immunity, methods of reducing infection, and the tolerance of the oocysts.

There are numerous illustrations and an appendix on technique together with an extensive bibliographic index and a general index render the contents of the book readily accessible.

To the biologist, the pathologist, the practitioner, and the breeder, this book should be of interest and value as correlating in a systematic manner the present information available concerning a subject about which there has been much confusion in the past.

### Recent Advances in Vaccine and Serum Therapy\*

THE purpose of this book is to survey the present state of knowledge regarding the employment of vaccines and sera in the prevention and treatment of disease.

Few will deny that there has been and still is more or less clinical confusion in this field and the present volume is, therefore, not only timely but fills, as well, a place long empty in the physician's reference library.

The book is divided into two parts. Part I, written by Dr. Petrie, is concerned with the prevention and treatment of disease by means of sera and with the specific prophylaxis and treatment of virus diseases in man and animals.

Part II, written by Professor Fleming, surveys the prevention and treatment of disease by means of vaccines.

An extraordinary amount of work has been done in both these fields, and the physician, laboratory worker, and student here finds it admirably surveyed and correlated.

The authors have not been satisfied merely to list or abstract the numerous investigations which have influenced present concepts in these fields, but present them in the light of their own experience, as a coherent and authoritative story, well conceived and well written.

The list of references presented at the end of each chapter evidences a careful and painstaking review of the literature and the extensive subject index as well as a complete and separate author index render the contents of the book readily accessible.

This volume should be on the reference shelf of every worker interested in this field and may be classed as indispensable for the physician who desires to utilize either sera or vaccines in an intelligent manner.

It may confidently be accepted as a valuable as well as highly practical reference work in this important field and recommended without reserve to the practicing physician.

### Manual of Determinative Bacteriology†

THE *Manual of Determinative Bacteriology* sponsored by the Society of American Bacteriologists and edited by Dr. Bergey has long been indispensable to clinical and bacteriologic laboratories and requires neither introduction nor labored comment.

This new fourth edition is enlarged by nearly 100 pages by amplification in the description of species and by the addition of about 50 species and one new genus.

Despite the thorough revision and the increased size of the book the price is unchanged. Were it twice as much the book would still be invaluable.

\*Recent Advances in Vaccine and Serum Therapy. By Alexander Fleming, Professor of Bacteriology, University of London, and G. F. Petrie, Bacteriologist-in-Charge, Serum Department, Pasteur Institute, Elstree. Cloth, pp. 463. 5 illustrations. P. Blakiston's Son and Co., Philadelphia, Pa.

†Manual of Determinative Bacteriology. By David H. Bergey. Cloth, pp. 664. Fourth edition. Williams & Wilkins Co., Baltimore, Md.

## Practical Methods in Biochemistry\*

WHILE intended primarily for medical students this manual should also prove useful to the physician, not only as a technical manual, but also as a work of reference concerning the principles and methods of biochemistry which now occupy so prominent a place in the practice of medicine.

The style is clear, simple, and easily understandable and the volume may be recommended as a comprehensive and reliable guide.

## A Textbook of Bacteriology†

FEW textbooks of bacteriology have attained a more lasting or more deserved popularity than that of Hiss and Zinsser, the new seventh edition of which, prepared by Zinsser and Bayne-Jones and dedicated to the memory of Dr. Hiss, now makes its appearance.

So familiar is this excellent text as a comprehensive and authoritative presentation of this subject that little need be said by way of introduction.

While extensively revised and in many ways rewritten, the original purpose of the book has been maintained, to present not only a treatise on the fundamental laws and technique of bacteriology, as illustrated by their application to the study of pathogenic bacteria, but also to serve as a manual of infectious diseases.

The scope of the work is indicated by the titles of the nine main sections into which it is divided: Part I, The General Biology of Bacteria and the General Methods of Bacteriology; II, Infection and Immunity; III, Pathogenic Microorganisms; IV, The Rickettsia Diseases; V, The Spirochetes; VI, Medical Mycology: Molds, Yeasts, Actinomycetes, and Pathogenic Fungi; VII, Diseases Caused by Ultramicroscopic Viruses, the Exanthemata, and Diseases of Uncertain Etiology; VIII, Outline of Diagnostic Methods of Medical Protozoology; IX, Technical Methods of Bacteriology, Immunology, and Serology.

The revision has been thorough and extensive and embodies consideration of all the many and marked advances which have been made within the last ten years in the field of bacteriology and immunology and includes a discussion of the contributions made in 1933 and the early part of 1934.

As before, the book constitutes an outstanding contribution in this field and one without which no reference library can be complete.

It can be enthusiastically recommended without reserve and, without doubt, will receive the same general approval as its predecessors.

\*Practical Methods in Bacteriology. By F. C. Koch, Professor of Physiological Chemistry, University of Chicago, Cloth, pp. 282. 17 figures. William Wood & Co., Baltimore, Md.

†A Textbook of Bacteriology. By Hanz Zinsser, M. D., Professor of Bacteriology and Immunology, Harvard University; and Stanhope Bayne-Jones, M.D., Professor of Bacteriology, Yale University Medical School. Ed. 7, cloth, pp. 1226, 174 illustrations. D. Appleton-Century Co., New York.

### Barnacles

**H**UMAN psychology perhaps to some extent may be reflected in its proverbs so that the time-worn sayings concerning the silver lining and the ill wind that, despite itself, blows some one some good all may justify the dictum that "hope springs eternal in the human breast."

Certain it is that not infrequently in the history of civilization great catastrophes, extraordinary plagues and similar events, regarded at the time as crushing and devastating blows to fortune, have been instead the starting points for tremendous advances and discoveries and have initiated a cycle of events productive of far-reaching benefits to humanity.

If history, as it is reputed to do, again repeats itself, perhaps the depression into which the world at large has been plunged for some years past and from which it shows faint but indubitable signs of beginning to emerge, may in its turn be productive of direct and indirect benefits.

It was inevitable under the circumstances that the social world should, in the face of its apparent collapse, take stock of the mechanism which holds it together and, as it were, makes it go; and very naturally medicine, in which term is included all that has to do with the management and control of disease and its congeners, has not escaped a critical glance.

Community responsibility for the care of the sick is an essential part of the development of civilization, for the discharge of which a huge structure has developed, ranking in importance, not only because of its essential necessity but also because of its economic magnitude and ramifications, with any of all those of which modern civilization can boast.

Hospitals are an integral part of this structure and, although not commonly regarded as "Big Business," properly belong in this category; for the seven thousand hospitals in the United States in round figures represent a capital investment of more than three billions of dollars, a capital sum exceeded by but few of the great industries.

It is entirely probable that there is little general appreciation of the fact that the average one hundred bed hospital represents an average capital investment of one million dollars and that the average investment per bed in accordance with the size and type of hospital, for acute or chronic diseases or including research facilities, varies from \$2,500 to more than \$10,000.

On the basis of the investment involved hospitals must be regarded as a business, "Big Business," the business of medical care, and the fact that this business ship within recent years has been laboring rather heavily in a heavy, stormy economic sea, as it were, has focussed attention upon this structure and the proposal by many individuals and groups of various measures to allay the storm and set the vessel once more on an even keel.

Oceans of ink have already been spilled in the discussion of what has popularly become familiar as "the cost of medical care" and the end of the avalanche of words and windy dispute is far from near, nor will it be found herein, for the subject is not to be dismissed within the limits of an editorial. Nor is any discussion here intended of the relation of hospital costs to the general costs of illness, important as it is. Those are matters deserving abler pens; these are but casual observations.

Above, the hospital structure with a striking lack of originality has been likened to a ship and a meager acquaintance with matters nautical—gathered, it must be confessed, from perusal of such authorities as Marryatt, the varied tales of Conrad, *Moby Dick*, and the reading (repeatedly) of *Treasure Island*—allow us to state with some confidence that when the good ship no longer shows her accustomed speed but, instead, merely lumbers along, wallowing ungracefully, the scraping from the bottom of barnacles and accumulated débris was a very common custom apparently productive of the desired result.

Can it be that hospitals in the course of time have accumulated any barnacles? Can it be that this huge structure has drawn to itself by custom or habit any accretions not perhaps essential per se to its efficiency or existence?

The business of hospitals, as already said, is the business of medical care and hence indissolubly associated with the practice of medicine and the physi-

cian. And physicians of late have had it brought rather forcibly to their attention that to some extent, varying under different circumstances and in different localities, the practice of medicine seems to have passed or to be passing from the hands of the physician into the hands of the hospital.

Now, while it has been possible in the past, and is still possible in the present, to carry on the business of taking care of the sick without the hospital, it is perhaps sometimes minimized if not overlooked that the hospital without the physician is rather a helpless if not useless institution. It is conceivable that there are hospital boards and perhaps, even superintendents to whom such an idea would appear preposterous, and it is not strange that this should be so when one pauses to consider how little, relatively speaking, the physician has to do with the running of hospitals.

True, as a dispensary worker he gives untold hours of his time freely and without remuneration to the care of patients, not a few of whom are without moral right or justification for such free treatment, and after often a lengthy period of service in this capacity, he graduates to the dispensing of free care under like circumstances in the wards, and sometimes, as at present, there comes some vague wonderment as to just how all this came about and whether or not he may not thereby be committing a sort of slow economic hara-kiri.

If, as is not at all beyond the bounds of possibility, the practice of medicine is to become a function of the social organization either permanently or temporarily until such time as the futility of such a program, despite its theoretical advantages, becomes evident in practice, the physician may well wonder just what place will be his in relation to the hospital.

Although the business of the hospital is the business of taking care of the sick, the physician is seldom indeed found directing its destiny in that respect, for custom seems to have decreed that hospital superintendents are most often graduate nurses. Just why this should be so; what basis there is for assuming that the training of a nurse implies executive ability or the ability to supervise rather than to assist in the care of the sick, is, it must be confessed, somewhat difficult to ascertain.

Yet the fact remains that perhaps a majority of hospitals of average size have nurses as superintendents, not infrequently directing the Board of Managers as well as the hospital and casting a supervisory eye over the activities of the staff. And, as some cynic once remarked: Hospitals are sometimes mismanaged because they are Miss managed.

If, in his extremity, the physician turns to the field of anesthesia, certainly an important one, properly a specialty of medicine and so largely regarded in England, here, too, he finds the nurse rather firmly ensconced.

There is no place for him on the Board of Managers, for it is only very recently that Staff representation has been granted as a favor.

He may strongly suspect that this or that free patient is well able to pay for treatment and belongs in the doctor's office rather than the dispensary, but the nurse or the lay social service worker has decreed otherwise, and that's that!

He finds himself arraigned and accused of grave responsibility for the high costs of medical care, and finds it somewhat difficult to reconcile the accusation with the fact that the money earmarked for payment of his bill has been swallowed up in payment of the hospital's.

And as the economic storm rages about him, he finds himself working for the hospital, carrying on the practice of medicine for it and nourishing thereby a host of lay personnel. Neither skipper, mate, nor even bos'n, small wonder that he wonders whether it were not better to be merely another barnacle.

### The Anemia of Pregnancy

WHILE the fact that pregnancy may be accompanied by a varying degree of secondary anemia is more or less commonly recognized, it is only within recent times that, possibly as an aftermath of studies in prenatal care, much attention has been paid to its presence or much effort expended upon the determination of its degree.

We refer, not to the severe hemolytic anemia, sometimes spoken of as the pernicious anemia of pregnancy, but to the definite secondary, though not always marked anemia which seems to be the result of pregnancy per se.

The pernicious or hemolytic anemia of pregnancy is encountered during the later months of pregnancy and the puerperium. Insidious in onset, it may reach a marked degree without the production of marked symptoms and thus may escape detection until attention is drawn to it by symptoms closely resembling those seen in true pernicious anemia.

The hemolytic anemia of pregnancy is the result of the action of a synectial hemolysin arising in the ectodermal cells of the chorion. Under normal conditions as pregnancy progresses an antihemolysin is formed in the maternal blood but when, for any reason, its formation is inhibited, the hemolytic anemia of pregnancy is the result.

Fortunately, in view of its rather high mortality, this form of anemia in pregnancy is rather uncommon.

The less marked but still definite secondary anemia of pregnancy, on the other hand, is very common and of definite significance although often overlooked when cytologic examinations of the blood are neglected as a part of the prenatal survey.

The findings of practically all observers who have reported upon this subject present a remarkable conformity.

Bland and Goldstein,<sup>1</sup> in a study of 50 cases, found a hemoglobin content ranging from 42 to 78 per cent (Dare) and erythrocyte counts of from 2.36 to 3.98 million cells per cubic millimeter.

In a second study of 300 cases, 100 being private cases, Bland, Goldstein and First,<sup>2</sup> found red cell counts below 3.5 million in 33.3 per cent of cases during the first two trimesters of pregnancy, 55.7 per cent in the third trimester, and 26 per cent during labor.

Galloway<sup>3</sup> in a study of 382 cases found average hemoglobin values (Sahli) of 73, 69, and 66 per cent for the first, second, and third trimesters respectively, and erythrocyte counts of 4.05, 3.94, and 3.87 millions per cubic millimeter evidencing both a chlorotic type of anemia as well as a definite progression as the pregnancy advanced.

Practically the same findings are reported by Kilduffe<sup>4</sup> in 300 cases as shown in Table I.

TABLE I

| DURATION OF<br>PREGNANCY,<br>MONTHS | NO. CASES | AVERAGE Hb.<br>(HADEN) |          | AVERAGE R.B.C.<br>MILLIONS PER<br>C. MM. |
|-------------------------------------|-----------|------------------------|----------|------------------------------------------|
|                                     |           | GM.                    | PER CENT |                                          |
| 1 - 3                               | 12        | 10.07                  | 73       | 4.50                                     |
| 4 - 6                               | 72        | 9.93                   | 72       | 3.73                                     |
| 7 - 9                               | 216       | 9.10                   | 66       | 3.73                                     |

It is unnecessary to cite the many other studies available, as all present comparable findings so that it may be accepted as proved that an anemia secondary to pregnancy per se is present in from 50 to 60 per cent of all cases, which shows a tendency to be somewhat chlorotic in type and a definite tendency to progress *pari passu* with the progression of the pregnancy.

The mechanism responsible for its production has been the subject of much discussion, many different theories having been advanced, none of which, however, have been definitely proved.

Thus, it has been attributed to hydremia producing a decreased iron content of the corpuscles, which would account for its chlorotic type; to poor hygiene or the presence of such diseases as nephritis, syphilis, and tuberculosis; to the continuation of a preexisting anemia; to focal infections; and to the expression of an "individual disposition" in accordance with the general physical well-being of the individual patient.

As stated, however, none of these conceptions has been susceptible of clear-cut, definite or indisputable proof.

The possible relation of this secondary anemia of pregnancy to the presence of the syncytial hemolysin held to be responsible for the hemolytic anemia mentioned above but inhibited in the case of the secondary by the later production of an antihemolysin is one of the oldest theories but, like all the others, still remains but a theory while its occurrence in the higher classes of patients, usually seen as private cases, robs environment factors of all significance.

Many investigators of this question assert that the anemia spontaneously disappears after delivery but many others are unable to find conclusive evidence of the correctness of this contention.

The matter still remains a problem awaiting solution, the present status of which may be thus summarized:

1. Pregnancy, per se, produces a secondary anemia somewhat chlorotic in type which progresses *pari passu* with the progression of pregnancy.

2. No satisfactory or demonstrable etiologic mechanism has yet been found.

3. In view of these facts, cytologic blood studies should be a part of routine prenatal care.

4. All patients with a hemoglobin below 75 per cent and erythrocyte counts under 3.5 million should be particularly observed and therapeutic measures instituted immediately upon the discovery of the deficiency. It is advisable also that such patients be watched for several months after delivery for evidence of bone marrow changes.

### Another Simple Rotary Inoculating Table

*To the Editor:*

Whether one has many or few Petri plates to stroke, a rotary table gives very satisfactory results and is a great convenience.

Quite a number of designs of such a piece of apparatus have appeared in the recent literature, requiring for construction the services of anyone from a blacksmith to a Swiss watchmaker.

We have found that the simplest and most satisfactory method of constructing such a machine is to take a two-dollar bill and go out and buy an old discarded portable Victrola. (Since the advent of Radio, one can sometimes get two dollars for taking the machine away.) If the reader cannot improvise from several old records ("She Knows Her Onions" or "On the Beach at Waikiki" preferred) and some thumb tacks, a means of holding the Petri plate on the revolving turntable, he should not be trusted with a platinum loop. With the brake the speed may be adjusted to suit the bacteriologist's artistic temperament.

We have used our machine for four or five years with utter satisfaction.

ERIC A. FENNEL, M.D.

HONOLULU, HAWAII, APRIL 10, 1934.

## SUBJECT INDEX

Abstracts are indicated by (Abst.) after the page number; book reviews, by (B. Rev.) after the page number.

### A

- Absorption of dextrose from the human gastro-intestinal tract, 1286
- Abstracts, 101, 211, 327, 430, 555, 671, 700, 905, 1021, 1138, 1216, 1315
- Acetanilid, influence of caffeine on effects of, 909 (Abst.)
- Acid filtrate, sulphosalicylic—note on the determination of blood urea by direct nesslerization of a sodium tungstate, 783
- Acidity, gastric, in thyroid dysfunction, 938 (Abst.)
- Actinomyces, modified Sabouraud medium for cultivation of acid-fast, 940 (Abst.)
- Adapter, new microscope for band spectroscopy, 755
- Adenoma, benign, of sweat glands, 586
- Adolescent male, a study of the red blood cell count and hemoglobin in, 172
- Agglutination, granular and floccular types of, with *B. typhosus*, a study of, 225
- H & O following typhoid vaccination and in an unselected group of individuals, 327 (Abst.)
- technic applied to *B. pertussis*, 558 (Abst.)
- Agglutinin content of blood following typhoid and paratyphoid immunization, 115 (Abst.)
- Agglutinins, developments in study of, 1114 (B)
- Agranulocytosis, etiology of, 709
- in childhood, 213 (Abst.)
- Air borne molds, 111 (B)
- Aleucemic myelosis, 1022 (Abst.)
- Alimentary tract, pyogenic bacteria in, of surgical maggots implanted in infected wounds, destruction of, 581
- sodium ricinoleate action in, an attempt to determine, 462
- Allergic skin reaction in brucella infection, a study of the opsonocytaphagic power of the blood and, 1021 (Abst.)
- Allergy, food, as a common problem, 53
- recent immunologic studies in hypersensitivity to tobacco, 793 (Abst.)
- and its influence upon  
1280  
with auricular fibrillation, a study of quindin effects on, 232
- Amebiasis, complement fixation test for, further studies on cultivation of *Endameba histolytica* and, 395
- Amebic dysentery, unusual experience with, 792 (Abst.)
- infection, epidemiology of, 795 (B)
- American Indian, medicine of, 1
- Amylase, salivary, in patients with pernicious anemia, a study of, 504
- Amytal, intravenous lethal doses of, in dog and rabbit and a table of animal dosages compiled from the literature, 1191
- Anatomy of Rhesus monkey, 912 (B. Rev.)
- Anemia, aplastic, 1139 (Abst.)
- analysis of so-called, 1023 (Abst.)
- chronic idiopathic hypochromic, 908 (Abst.)
- etiology and treatment of, in pregnancy, 1249 (Abst.)
- macrocytic in disease of liver, 1022 (Abst.)
- nutritional, of rat, effect of various colloidal and crystalloidal metallic compounds in, 1053
- of pregnancy, 1378 (B)
- pernicious, salivary amylase in patients with, a study of, 504
- production of erythrocytes, reticulocytes, and hemoglobin in, 967 (Abst.)
- sickle-cell, 507
- with autopsy finding, a fatal case of, 126
- Anesthesia, morphine pentobarbital, for dog surgery, 202
- Anesthetics, local, Diazo reaction for detection of certain, in urine and in tissues, 1018
- pharmacology of, studies in, 120
- Aneurysm formation in children, verrucous aortitis with special regard to, 929
- Angina, hypoleucocytic, 311
- Anilin dye poisoning, methylene blue as an antidote for, 166
- small, 1135
- functional studies of
- Anticoagulants, changes in cell volume produced by varying concentrations of different, 777
- Antidote for anilin dye poisoning, methylene blue as an, 166
- Antigen, Eagle, a study of, for Wassermann and flocculation tests, 81
- for Henry's reaction, a new, 1023 (Abst.)
- Antileptic dye, penetration of an, demonstration of, into tissues of genitourinary tract, 735
- Antisheep hemolysin, production of, a new method for, 666
- Antisera, refining of, 1324
- Aortitis, verrucous, with special regard to aneurysm formation in children, 929
- Aplastic anemia, 1139 (Abst.)
- analysis of so-called, 1023 (Abst.)
- Apparatus, combination condensing and receiving vessel, 1116
- dog-operating table, 1117
- electrical tool, a simple and efficient, for sealing museum jars, 197
- for continuous administration of fluid intravenously, 768
- for determination of metabolic rate in guinea pigs, a simple and inexpensive, 510
- perfusion, an easily assembled, self-recording, 89
- Aqueous extracts of streptococci, treatment of rheumatic carditis with, 695
- Arterial blood in cancer, reaction of, 909 (Abst.)
- Artery, pulmonary in heart disease, embolism and thrombosis of large branches of, 265
- Arthritis, chronic, glutathione content of blood in, and rheumatoid conditions, 1151
- rheumatoid, 1142 (Abst.)
- and mixed, sedimentation rate and polymorphonuclear count in, 830
- Arcites, drainage of, observations on vascular response to, 948
- Auricular fibrillation, ambulatory patients with, a study of quindin effects on, 232
- Auriculo-pericardial fistula, dynamic consequences of, 1091
- Automatic and graphic method of recording diuresis, 81
- Automatic-filling ink recording system and permanent type water manometer, 1342
- Autonomic imbalance in animals, 1184
- Autopsy stand for mice, a simple, 210

### B

- Bacilli, tubercle, routine culture of urine for, 675 (Abst.)
- typhoid, isolation of, from water and sewage, 559 (Abst.)
- Bacillus abortus, guinea pigs inoculated with, intracutaneous reactions induced in, 589
- coli hemolyticus, clinical significance of, 1024 (Abst.)
- pertussis, rapid agglutination on technic applied to, 558 (Abst.)

## Bacillus, Cont'd

- proteus pseudovaleriae (De Assis), a typhoid-like infection associated with an organism resembling, 1091  
 toxin of, 870  
 tuberculosis, inhibitory effect of normal blood on growth of, at incubator temperature, 679 (Abst.)  
 viability and virulence of old cultures of, 790 (Abst.)  
 typhosus, granular and floccular types of agglutination with, a study of, 225
- Bacteria, behavior of bacteriophage and, in lesion after treatment of acute staphylococcus skin infections with bacteriophage, 1257  
 pathogenic, in immune blood, growth of, 77  
 pyogenic, in the alimentary tract of surgical maggots implanted in infected wounds, destruction of, 581
- Bacterial culture media, clearing of heavy, an adaptation of sand filtration to rapid, 195  
 endocarditis, subacute, streptococci that resemble diphtheroids recovered from blood cultures in, significance of, 1301  
 filtration, simplifying the mechanics of, 786  
 bactericidal and fungicidal action of homologous halogen phenol derivatives and its "quasi-specific" character, 835  
 bacteriologic incubator, an improvised, 1095  
 bacteriology, manual of determinative, 1353 (B. Rev.)  
 of veterinary, 221 (B. Rev.)  
 textbook of, 1351 (B. Rev.)
- Bacteriophage, studies in, 1257  
 Bacterium melanogenicum, 689  
 Barnacles, 1355 (E)
- Basal metabolism of old people, 1073  
 Benign adenoma of the sweat glands, 586  
 Bicycle ergometer, recording electrodynamic brake, 1105
- Bile, bilirubin in, quantitative estimation of use of hydrogen peroxide in, 743  
 constituents of, a method for the separation of the principal, 1003  
 pigments, studies on quantitative estimation of, 723  
 salts, combined effects of, and oleic acid on choleresis, 567
- Biliary acids in body fluids, a new colorimetric method for the determination of, 523  
 tract, diagnostic methods and metabolic studies in disease of, 215 (Abst.)  
 moniliasis of, 379
- Bilirubin, concentration and precipitation of, in the gallbladder and bile ducts, 327 (Abst.)  
 in bile, quantitative estimation of, use of hydrogen peroxide in, 743  
 plasma, estimation of, 1122  
 spectrophotometric investigation and determination of, 593
- Biochemistry, practical methods in, 1351 (E. Rev.)
- Biologic specimens, preservation of, 774  
 Biopsy, present status of, 560 (Abst.)
- Blood, agglutinin content of, following typhoid and paratyphoid immunization, 445 (Abst.)  
 and urine, chloral hydrate in, quantitative determination of, 1332  
 arterial, reaction of, in cancer, 909 (Abst.)  
 calcium, after the oxalate to . . . . .  
 roidectomy . . . . .  
 catalase in heart disease, 133  
 cell and hemoglobin relations as determined by iron and oxygen capacity methods, 889  
 count, red, and hemoglobin in the adolescent male, a study of, 172  
 white, dilution pipettes, the calibration of, 95  
 cells in, determination of volume of, centrifuge method for, 757  
 chemistry, nonprotein nitrogen studies and their prognostic significance in acute coronary occlusion, 441 (Abst.)  
 cholesterol in chronic nephritis and retention uremia, 906 (Abst.)

## Blood, Cont'd

- concentration incident to shock, changes in, 295  
 corpuscles, red, a dropper for performance of fragility test of, 1009  
 count, Schilling differential, in tropical diseases, 614  
 culture, an improved method of, 203  
 in tuberculosis, 1021 (Abst.)  
 cultures, comparative study of, taken with Kendall and routine mediums, 105 (Abst.)  
 in subacute bacterial endocarditis, significance of streptococci that resemble diphtheroids recovered from, 1301  
 cytology in treated and untreated syphilis, 1023 (Abst.)  
 during first year of life, 791 (Abst.)  
 fibrinogen, in quantitative determination of, 906 (Abst.)  
 following glucose ingestion, variations of urea, total nonprotein nitrogen and chloride concentration in, 474  
 glutathione content of, in chronic arthritis and rheumatoid conditions, 1151  
 relation of, to hemoglobin and amount of red cells, 395  
 in normal pregnancy, 1142 (Abst.)  
 immune, growth of pathogenic bacteria in, 77  
 inhibitory effect of normal, on growth of B. tuberculosis at incubator temperature, 679 (Abst.)  
 iodine studies, 818, 806  
 iron and hemoglobin, a clinical study of, 362  
 in human, 212 (Abst.)  
 is halometry reliable, 1351 (Abst.)  
 lipase in patients with peptic ulcer, 1054  
 lipids in children with scarlet fever and rheumatic disease, 1246 (Abst.)  
 lipid content of, observations upon the Lipokrit method for the determination of, 411  
 normal, presence of biliary acids in, a note on the alleged, 523  
 pellagra, a chemical peculiarity of, 329 (Abst.)  
 picture, 333 (B. Rev.)  
 in oral infection, 1070  
 plasma proteins, plasma viscosity and suspension stability of, in dogs, relative effects of diathermy and infection on, 571  
 proteins, a micromethod for quantitative estimation of, 555 (Abst.)  
 red cells in man, elliptical, 612  
 sedimentation, interrelation of Cutler, Linzenmeier and Westergren tests, 1140 (Abst.)  
 time of, 1010  
 serum, light filtering index of, 765  
 of normal children, concentration of calcium and phosphorus of, 679 (Abst.)  
 tryptophane content of, 1113  
 specific gravity of, in human cancer, 983  
 stain, Wright's, modified technic for making, 438  
 studies in hyperthyroidism, 371  
 in normal pregnancy, 1248 (Abst.)  
 study of a lymphocytic hemogram, 330 (Abst.)  
 sugar curves, comparison of, when glucose is given orally and intraduodenally, 608  
 in schizophrenia, 792 (Abst.)  
 transfusion, velocity factor in, 1206  
 urea, determination of, . . . . .  
 tion of a sodium . . . . .  
 cyclic acid filtrate, . . . . .  
 nitrogen in, direct nesslerization method for, where commercial urease is employed, 659  
 uric acid in human, bovine, and avian, a comparison of methods for determination of, 892  
 whole, cholesterol in, a simplified microdetermination of, serum and plasma, 883  
 in paresis, effect of hyperpyrexia upon phosphorus partition of, 1015
- Body fluids, biliary acids in, a new colorimetric method for the determination of, 523  
 cytologic study of, 315

Book reviews, 108, 220, 333, 417, 911, 1020, 1352  
 Brain, ethyl alcohol in, estimation of, 1014  
 Breast, carcinoma of, bases for histologic grading of, 677 (Abst.)  
 Bright's disease, fractional phenolsulphonaphthalein test in, 331 (Abst.)  
 Broncho . . . . . of fusospiro-  
 . . . . . small doses of  
 . . . . . of, 68  
 Brucella infection, allergic skin reaction in, a study of the opsonocytaphagic power of the blood and, 1021 (Abst.)

C

Cage for mice and rats, 1020  
 metabolism, for rats, 669  
 small animal metabolism, 1135  
 Calcium and phosphorus, concentration of, in blood serum of normal children, 679 (Abst.)  
 metabolism and calcium therapy, 108 (B. Rev.)  
 serum, in normal boys, 410 (Abst.)  
 Calibration of white blood cell dilution pipettes, 95  
 Cancer, human, specific gravity of blood in, 983  
 reaction of arterial blood in, 909 (Abst.)  
 Carbohydrate tolerance, effect of gain in weight on, 1109  
 Carcinoma, breast, bases for histologic grading of, 677 (Abst.)  
 of pancreas, 1058  
 primary, of lung, 676 (Abst.)  
 Cardiovascular system or kidneys, serum proteins in diseases not primarily affecting, 1348 (Abst.)  
 Carditis, rheumatic, treatment of, with aqueous extracts of streptococci, 695  
 Catalase, blood, in heart disease, 133  
 Catarrhal jaundice, liver function in, 791 (Abst.)  
 Cell morphology, study of, a differential stain that advances, 1247 (Abst.)  
 volume, changes in, produced by varying concentrations of different anticoagulants, 777  
 packed, normal erythrocyte, and hemoglobin standards in young men, 851  
 Cells in blood, determination of volume of, centrifuge method for, 757  
 Cellular multiplication, sulphydryl and, 680 (E)  
 Central nervous systems, histopathology of the peripheral and, 220 (B. Rev.)  
 Centrifuge method for the determination of the volume of cells in blood, 757  
 Cerebrospinal fluids, M.K.R. in, a new syphilis reaction, 518  
 Cervical mucus, variations of solubility of, in relation to the menstrual cycle, 358  
 Chemistry of the skin, studies of physiologic and pathologic, 654  
 Chemotherapeutic studies with sodium ricinoleate (soricin), 972  
 Children, aneurysm formation in, verrucous aortitis with special regard to, 929  
 pneumonia in, in Egypt, the causative organisms of, 751  
 Chloral hydrate, quantitative determination of, in blood and urine, 1332  
 Chloramines, use of, for disinfection of swimming pools, some factors involved in, 1346 (Abst.)  
 . . . . . blood following  
 . . . . . variations of urea,  
 . . . . . ogen and, 474  
 . . . . . 911 (B. Rev.)  
 . . . . . of patients with,  
 . . . . . in, 959  
 Cholera, combined effects of bile salts and oleic acid on, 567  
 Cholesterol, blood, in chronic nephritis and retention uremia, 906 (Abst.)  
 simplified microdetermination of, in whole blood, serum, and plasma, 883  
 Chronic myelosis in children, 713  
 Cisternal drainage, pneumococcal meningitis with recovery following, report of a case of, 1139 (Abst.)  
 Coccidia and coccidiosis, 1352 (B. Rev.)  
 Coccidioides immitis, a simple technic for finding, 1013

Cold, common, 333 (B. Rev.)  
 Colds, common, nasopharyngeal flora and some remarks as to their relation to, 877  
 Colloidal and crystalloidal metallic compounds in nutritional anemia of rat, effect of various, 1083  
 carbon solutions, preparation and use of, 986  
 gold test, Lange, a modification of, 1007  
 lead compounds, 178  
 Colon, irritable, treatment of, with sodium . . . . . 231  
 . . . . . for the determination of  
 . . . . . in body fluids, a new,  
 523  
 rapid, for multiple determinations of uric acid, 650  
 Complement fixation test for amebiasis, further studies, ameba histology  
 Condenser, reflux, a . . . . .  
 Corn component of a . . . . .  
 . . . . . bility in, 390  
 Coronary blood supply, to experimentally produced ventricular lesions, relationship between, and resulting electrocardiographic alterations, 1040  
 occlusion, acute, serial nonprotein nitrogen studies and their prognostic significance in, 441 (Abst.)  
 and sudden death, 1272  
 Corpuscles in health and disease, partition of potassium between serum and, 633  
 Correspondence, 451, 1360  
 Corynebacterium diphtheriae gravis found in Maryland, 943  
 Cranial nerves, outline of, 108 (B. Rev.)  
 Crystalline elements in the stomach lavage of patients with cholelithiasis, 950  
 Crystalloidal and colloidal metallic compounds in nutritional anemia of rat, effect of  
 . . . . . differential, for B. diph-  
 . . . . . theriae and B. pseudodiphtheriae, 439 (Abst.)  
 Cytologic study of body fluids, 315

D

Dermatitis, contact, patch test in diagnosis of, 555 (Abst.)  
 Dermatology, history of, 447 (B. Rev.)  
 Device, pipette washing, 94  
 Dextrose, absorption of, from the human gastrointestinal tract, 1286  
 . . . . . blood count Schilling, in tropical  
 . . . . . in, 1021 (Abst.)  
 . . . . . and trends of dia-  
 . . . . . betes mortality throughout world, 678 (Abst.)  
 mineral water in management of, experi-  
 ments in use of, 1088  
 use of synthalin, 1067  
 mortality throughout world, characteristics and trends of, 678 (Abst.)  
 Diathermy and infection, relative effects of, on plasma proteins, plasma viscosity and suspension stability of blood in dogs, 571  
 Diazo reaction for detection of certain local anesthetics in urine and in tissues, 1018  
 Dietary treatment of undernutrition, 1169  
 . . . . . aine poisoning, 875  
 . . . . . of jaundice, use of galac-  
 Digestion process, microKjeldahl, a simple device to be used in connection with, 672  
 Digestive disorders, phytopharmacology of . . . . .  
 . . . . . stc  
 . . . . . nit  
 Diothane . . . . . 771  
 Diphtheria . . . . .  
 . . . . . against, by  
 . . . . . a . . . . . (st.)  
 differential culture medium for B. diph-  
 theriae and B. pseudodiphtheriae, 439 (Abst.)  
 precipitated toxoid as an immunizing agent against, 1021 (Abst.)  
 Diuresis, method of recording, an automatic and graphic, 81  
 Diuretics, xanthine, comparative study of cer-  
 tain, 248

Dog-operating table, 1117  
 Drainage of ascites, observations on vascular response to, 918  
 Drinking fountain, improved, for small laboratory animals, 312  
 Dropper for performance of fragility test of red blood corpuscles, 1009  
 Duodenal pouches, a method of preparing, for use in experimental work, 1126  
 Dysentery, amebic, unusual experience with, 792 (Abst.)

## E

Eagle antigens for Wassermann and flocculation tests, a study of, 84  
 Edema, thrombophlebitic, effect of salyrgan and X-ray on rate of disappearance of, 243  
 Editorial, Anemia of pregnancy, 1358  
 Barnacles, 1355  
 Developments in the study of agglutinins, 1144  
 Epidemiology of amebic infection, 795  
 Erythrocyte diameters, 335  
 Have hospitals attained a standard of mediocrity, 1251  
 Hazards of statistical interpretation, 911  
 Hyperinsulinism, 222  
 Laboratory diagnosis of undulant fever, 1029  
 Origin of syphilis, 418  
 Some pitfalls in the study of sex hormones, 561

Sulphydryl and cellular multiplication, 680  
 Eggs, nutrient quality of, for growing tubercle bacilli, 410 (Abst.)  
 Egypt, pneumonia in children in, causative organisms of, 751  
 Electrode for measurement of potentials on the human body, an improved, 1231  
 Electrodynamical brake bicycle ergometer, the recording, 1105  
 Embolism and thrombosis of large branches of the pulmonary artery in heart disease, 265  
 Endameba histolytica, cultivation of, further studies on, and a complement fixation test for amebiasis, 495  
 Endo medium, nature of reaction of colon organism on, 412 (Abst.)  
 Endocarditis, subacute bacterial significance of streptococci that resemble diptheroids recovered from blood cultures in, 1304  
 Enteritis, acute, in infants and young children, 1248 (Abst.)  
 polytropic, 909 (Abst.)  
 Eosinophilia, induction of, in normal animals, 909 (Abst.)  
 reflex, 486  
 Epidemiology of amebic infection, 795 (E)  
 of pneumonia, 675 (Abst.)  
 of syphilis, history and, 447 (B. Rev.)  
 Epithelial cysts of the skin tissue, traumatic, 1250 (Abst.)  
 Ergebnisse der medizinischen Strahlenforschung, 1027 (B. Rev.)  
 Ergometer, recording electrodynamical brake bicycle, 1105  
 Erysipeloid among workers in a bone button factory due to the bacillus of swine erysipelas, 1021 (Abst.)  
 Erythrocyte diameters, 335 (E)  
 normal, hemoglobin and packed cell volume standards in young men, 851  
 production of, reticulocytes, and hemoglobin in anemia, 907 (Abst.)  
 Ethyl alcohol in brain estimation of, 1014  
 Experimental studies on nembutal (pentobarbital-sodium), 738

## F

Feces, a convenient specimen container, 328 (Abst.)  
 Fermentation tubes, Smith, and "U" tubes, special rack for, 553  
 Fibrinogen, quantitative determination of, in blood, 906 (Abst.)  
 Filter, light, for microblood sugar determinations, 607  
 Filterable virus diseases in man, 221 (B. Rev.)  
 Filtering index, light, of blood serum, 705  
 Filtrate, sulphosalicylic acid—note on the determination of blood urea by direct nesslerization of a sodium tungstate, 783

Filtration, bacterial, simplifying the mechanics of, 786  
 Fistula, auriculopericardial, dynamic consequences of, 1091  
 Flocculation test, study of Eagle antigens for Wassermann test and, 81  
 Vernes, In tuberculosis, 905 (Abst.)  
 tests for syphilis, 558 (Abst.)  
 Fluid, spinal, sugar determinations in experimental hypoglycemia of dogs, 1019  
 Food allergy as a common problem, 53  
 Food-borne infections and intoxications, 913 (B. Rev.)  
 Fragility test of red blood corpuscles, a dropper for performance of, 1009  
 Friedman rabbit ovulation test in differential obstetric diagnosis, 1033  
 test for pregnancy, observations on the technique of, 1221  
 Frozen sections, preparation and staining of, 201  
 Functional studies of patients on antiarthritic medication, 21  
 Fungicidal power of phenol derivatives, 1216  
 Fusospirochetal disease, oral spirochetes and related organisms in, 109 (B. Rev.)  
 etiology with small doses of neosalvarsan, treatment of bronchopulmonary suppuration of, 66

## G

Galactose in differential diagnosis of jaundice, use of, 1311  
 Gallbladder and bile ducts, bilirubin in, concentration and precipitation of, 327 (Abst.)  
 Gastric acidity in thyroid dysfunction, 905 (Abst.)  
 examination in pulmonary tuberculosis with negative sputum examination, 411 (Abst.)  
 Gastroenterology, modern aspects of, 221 (B. Rev.)  
 Gastrointestinal tract, absorption of dextrose from the human, 1286  
 Genitourinary tract, penetration of an antiseptic dye into tissues of, demonstration of, 735  
 Glucose, given orally and intraduodenally, comparison of blood sugar curves when, 608  
 Ingestion, blood following, variations of urea, total nonprotein nitrogen, and chloride concentration, 474  
 Glutathione content of blood in chronic arthritis and rheumatoid conditions, 1151  
 Gold test, Lance colloidal, a modification of, 1007  
 Gonococci, cultivation of, 557 (Abst.)  
 preparation of correct picture and simple culture method of, 1130 (Abst.)  
 Gram property of acid-fast form of tubercle bacillus, 350  
 stain of Much, modified, 422  
 Granular and floccular types of agglutination with B. typhosus, a study of, 225  
 Granuloma inguinale, further studies on etiology of, 910 (Abst.)  
 Granulopenia, etiology of, 799  
 Growth hormone, the inactivation of, 63  
 Guinea pigs inoculated with B. abortus, intracutaneous reactions induced in, 589  
 metabolic rate in, simple and inexpensive apparatus for determination of, 340  
 Gum dammar for use as a mounting media, purification of, 325

## H

Halogen phenol derivatives, homologous, bactericidal and fungicidal action of, and its "quasi-specific" character, 835  
 Handbuch der biologischen Arbeitsmethoden, 1027 (B. Rev.)  
 der Chemotherapie, 1028 (B. Rev.)  
 Hay fever, perennial treatment of, 481  
 Heart disease, blood catalase in, 135  
 criteria for the classification and diagnosis of, 109 (B. Rev.)  
 embolism and thrombosis of large branches of pulmonary artery in, 265  
 stroke volume of, determination of, 904  
 Hemoglobin and blood cell relations as determined by iron and oxygen capacity methods, 886

Hemoglobin, Cont'd  
 content of blood in infants, 107 (Abst.)  
 clinical study of blood iron and, 302  
 determination of, by iron content method, 406  
 in the adolescent male, a study of the red blood cell count and, 172  
 normal erythrocyte and packed cell volume standards in young men, 851  
 production of, erythrocytes and reticulocytes in anemia, 907 (Abst.)  
 relation of blood glutathione to, and amount of red cells, 395  
 Hemogram, lymphocyte, a study of, 333 (Abst.)  
 Hemolysis, antishoop, production of, a new method for, 666  
 Hemolytic properties of streptococci mastitis, 1347 (Abst.)  
 streptococci isolated from hemorrhagic smallpox, studies on, 280  
 Hemorrhagic smallpox, hemolytic streptococci isolated from, studies on, 280  
 Hepatic function, levulose and galactose tolerance tests for, clinical values of, 412 (Abst.)  
 Hill's radiopaque mass for the injection of lumina, a modification of, 1241  
 Histochemical studies of organs of tumor-bearing rats by the micromelneration method 1293  
 Histopathology of the peripheral and central nervous systems, 220 (B. Rev.)  
 Hodgkin's disease, a probable unusual case of, 625  
 Hormone diagnosis of viability of pregnancy, 674 (Abst.)  
 growth, the inactivation of, 63, 401  
 Hormones, sex, some pitfalls in the study of, 561 (E)  
 Hospital routine, demonstration of tubercle bacilli for use in, an evaluation of three methods for, 429  
 Hospitals attained a standard of mediocrity, have, 1251 (E)  
 Human body, measurement of potentials on, an improved electrode for, 1234  
 mind, a view of, and how it works, 220 (B. Rev.)  
 Hydatidiform mole, differentiation of pregnancy and, 216 (Abst.)  
 Hydrogen ion concentration, determination of, of normal and malignant tissues with the glass electrode and vacuum tube null indicator, 1100  
 peroxide, use of, in quantitative estimation of bilirubin in bile, 743  
 Hydrolyzed adrenalin as a tissue stain, on the importance of, 954  
 Hyperglycemia, hypertension, obesity and, 441 (Abst.)  
 Hypertension, 222 (E)  
 follow-up study of 30 (Abst.)

## R

- Rabbit ovulation test, Friedman, in differential obstetric diagnosis, 1033
- Radiopaque mass, Hill's, for the injection of lumina, a modification of, 1241
- Rachitogenic diet, variability in corn component of, 390
- Rack for Smith fermentation tubes and "U" tubes, 553
- Reaction, Diazo, for detection of certain local anesthetics in urine and in tissues, 1018 on a brown skin-adrenalin color, 951 Sachs-Witebsky, for diagnosis of syphilis, value of, 907 (Abst.) sedimentation in the newborn, 944
- Reactions, intracutaneous, induced in guinea pigs inoculated with *B. abortus*, 589 Kolmer, Kahn, and Meinicke, in the tropics, 780
- Recording system, an automatic-filling ink, and permanent type water manometer, 1342
- Red Blood cell count and hemoglobin in the adolescent male, a study of, 172 diameters, 333 (B. Rev.) cells in man, elliptical, 612 corpuscles, fragility test of, a dropper for performance of, 1009
- Reflex eosinophilia, 486
- Renal function, fractional phenolsulphonethalein test in Bright's disease, 331 (Abst.) in persons with one kidney, 329 (Abst.) tests, normal variations in, 329 (Abst.)
- Respiration of rabbits, Krogh type of spirometer for studying, a method of damping, 1334
- Reticuloocytes, 1120 new method of enumeration, 443 (Abst.) production of, erythrocytes and hemoglobin in anemia, 907 (Abst.)
- Reticulo-endotheliosis, leucemia, 1250 (Abst.)
- Rheumatic carditis, treatment of, with aqueous extracts of streptococci, 695 disease, blood lipids in children with scarlet fever and, 1246 (Abst.) fever, intravenous vaccination with streptococci, 908 (Abst.)
- Rheumatoid and mixed arthritis, sedimentation rate and polymorphonuclear count in, 830 arthritis, 1142 (Abst.) conditions, glutathione content of blood in chronic arthritis and, 1151
- Ricinoleate, sodium, 462, 468 chemotherapeutic studies with, 972
- Rosenthal, Kolmer-Wassermann, and Kahn tests for syphilis, comparison of, 1337
- Rotary inoculating table, a simple, 668

## S

- Salivary amylase in patients with pernicious anemia, a study of, 504
- Salmonella sulpestifer infection in a child, 678 (Abst.) in man, 211 (Abst.) and x-ray on the rate of of thrombophlebitis
- Sand filtration, an adaptation of, to rapid clearing of heavy bacterial culture media, 195
- Scarlet fever and rheumatic disease, blood lipids in children with, 1246 (Abst.) effect of tonsillectomy on the development of immunity to, as shown by Dick test, 216 (Abst.) blood count in tropical
- Schizophrenia, blood sugar in, 792 (Abst.)
- Schultz-Charlton test, 1022 (Abst.)
- Secretary, medical, 110 (B. Rev.)
- Sedimentation rate and polymorphonuclear count in rheumatoid and mixed arthritis, 830 reaction in the newborn 944 test in dermatology, 215 (Abst.) time of blood, 1010
- Semen, a differential stain that advances the study of cell morphology, 1247 (Abst.)
- Serology of syphilis, studies in, 621

- Serum and corpuscles in health and disease, partition of potassium between, 633 blood, light filtering index of, 705 tryptophane content of, 1113 calcium, in normal boys, 440 (Abst.) cholesterol in whole blood, plasma and, a simplified microdetermination of, 553 protein, determination of, by measurement of volume of precipitate, 1320 diagnostic value of changes in kaku azar, 558 (Abst.) in diseases not primarily affecting the cardiovascular system or kidneys, 1348 (Abst.) test for syphilis, choosing, 275 therapy and vaccine, recent advances in, 1353 (B. Rev.)
- Sex determination test of Dorn and Sugarman, 1347 (Abst.) hormones, some pitfalls in the study of, 561 (B)
- Sharpener for microtome knives, a simple automatic 199
- Shock, blood concentration incident to, changes in, 295
- Sickle cell anemia, 507 with autopsy findings, a fatal case of, 126
- Silicosis, pathology of so-called acute, 1351 (Abst.) silica content of lungs of a group of tunnel workers, 1351 (Abst.) silicon dioxide content of lungs in health and disease, 219 (Abst.)
- Silver nitrate reaction and its applicability to diagnosis of diseases of liver, 903 (Abst.)
- Skin, chemistry of, studies of physiologic and pathologic, 651 temperature, effect of smoking on, 962 test, intracutaneous, comparison of relative values of, and of pathogen-selective culture in selecting bacteria for vaccines from mixed cultures, 439 (Abst.) value of, with type-specific capsular polysaccharide in serum treatment of Type I pneumococcus pneumonia, 441 (Abst.) tissue, traumatic epithelial cysts of, 1250 (Abst.)
- Skin-adrenalin color reaction, on a brown, 951
- Smallpox, hemorrhagic, hemolytic streptococci isolated from, studies on, 280
- Smith fermentation tubes and "U" tubes, special rack for, 553
- Smoking, effect of, on skin temperature, 962 Sodium oxalate to normal and thyroparathyroidectomized cats, a study of blood calcium after the administration of, 142
- ricinoleate, 462, 468 chemotherapeutic studies with, 972 treatment of irritable colon with, 234 taurocholate and virulence of human tubercle bacilli, 1179
- Sorlein (sodium ricinoleate), chemotherapeutic studies with, 972
- Specific gravity of blood in human cancer, 953
- Spectrophotometric investigation and determination of bilirubin, 593
- Spectroscope, hand, a new microscope adapter for, 755
- Spezifität der serologischen Reaktionen, 913 (B. Rev.)
- Spinal fluid in meningitis, lactic acid of, 219 (Abst.) sugar determinations in experimental hypoglycemia of dogs, 1049 Wassermann and Kahn reactions upon, a comparison of, in treated and untreated cases of paresis, 546
- Spirocheta pallida, a new method of staining, 532 (Abst.)
- Spirochetes, oral, and related organisms in fusospirochetal disease, 108 (B. Rev.)
- Spirometer for studying the respiration of rabbits, a method of damping the Krogh type of, 1334
- Spleen visualization, mechanics of, by means of metallic compounds, in particular thorium, 511
- Sputum examination, pulmonary tuberculosis with negative, gastric examination in, 441 (Abst.)

Sputum, Cont'd  
 number of tubercle bacilli in, a technic for estimating, 928 (Abst.)  
 tubercle bacilli in, heavy drop method for demonstration of, 445 (Abst.)  
 Stain, differential, that advances study of cell morphology, 1247 (Abst.)  
 tissue, hydrolyzed adrenalin as, on importance of, 954  
 Staining of frozen sections, preparation and, 204  
 Staphylococcus skin infections, treatment of acute, with bacteriophage, behavior of bacteriophage and bacteria in lesion after, 1257  
 Statistical interpretation, hazards of, 914 (E)

   urea clearance, in pregnancy, 677 (Abst.)  
   Wassermann and flocculation, study of Eagle antigens for, 84  
 Testis, malignant teratoma of, metastatic tumor of tricuspid valve arising in case of, 749  
 Tetanus antitoxin, development of, following administration of tetanus toxoid, 1139 (Abst.)  
 Thorium compound, mechanics of spleen visualization of means of, 511  
 Thrombophlebitic edema, effect of salyrgan and x-ray on rate of disappearance of, 243  
 Thrombosis, femoral, complicated by, New Jersey outbreak of trichinosis, with report of a case, 1350 (Abst.)  
   of large branches of pulmonary artery in heart disease, embolism and, 265  
 Thymic hyperplasia, follow-up study of 30 cases of, 1216 (Abst.)  
 Thyroid disease, blood cholesterol in, effect of treatment on, 104 (Abst.)  
   dysfunction, gastric acidity in, 908 (Abst.)  
 Thyroparathyroidectomized cats, a study of blood calcium after administration of sodium oxalate to normal and, 142  
 Tissue, normal and malignant, determination of pH of, with glass electrode and vacuum tube null indicator, 1100  
   penetration of an antiseptic dye into, of genitourinary tract, demonstration of, 735  
   pH of formalin—a factor in fixation, 1024 (Abst.)  
   skin, traumatic epithelial cysts of, 1250 (Abst.)  
   stain, hydrolyzed adrenalin as, on importance of, 954  
 Toxemias of pregnancy, 923  
 Toxin of bacillus proteus, 870  
 Transfusion, blood, velocity factor in, 1206  
 Trichiniasis, diagnosis of, use of an intradermal test in, 1349 (Abst.)  
 Trichinosis, Bachman intradermal test in human, 1350 (Abst.)  
   New Jersey outbreak of, with report of case complicated by femoral thrombosis, 1350 (Abst.)  
 Trichophytin test, report of 350 cases, 213 (Abst.)  
 Tricuspid valve, metastatic tumor of, arising in a case of malignant teratoma of testis, 749  
 Tryptophane content of blood serum, 1113  
 Tubercle bacillus, acid-fast form of, gram property of, 350  
   bacilli, examination for, 885  
   experiences gained from, for use in hospital of three methods, 429  
   in sputum, heavy drop method for demonstration of, 445 (Abst.)  
   nutrient quality of eggs for growing, 440 (Abst.)  
   routine culture of urine for, 675 (Abst.)  
   virulence of human, sodium taurocholate and, 1179  
 Tuberculin, ointment patch test, 1138 (Abst.)  
   test, value of negative intracutaneous (Mantoux) test in adults, 1141 (Abst.)  
 Tuberculosis, blood culture in, 1021 (Abst.)  
   effect of vaccination with B. C. G. on children from tuberculous families, 1347 (Abst.)  
   etiology of, 108 (B. Rev.)  
   hematological retrospect, 792 (Abst.)  
   pulmonary, advanced, liver function in, 794 (Abst.)  
   comparison of blood sedimentation rate and Vernes flocculation test in, 212 (Abst.)  
   effect of exercise on leucocyte count in, 443 (Abst.)  
   gastric examination in, with negative sputum examination, 441 (Abst.)

- Tuberculosis, pulmonary, Cont'd  
 question of tubercle bacilli in blood in advanced, 102 (Abst.)  
 vitamin therapy in, 966  
 sanocrysin treatment, 444 (Abst.)  
 surgical, diagnosis of, 309  
 technic for estimating number of tubercle bacilli in sputum, 328 (Abst.)  
 tuberculin patch test in, 106 (Abst.)  
 Vernes flocculation test in, 905 (Abst.)  
 Tularemia, culture medium for rapid growth of *P. tularensis* in, 214 (Abst.)  
 treated by a new specific antiserum, 1141 (Abst.)  
 Tumor, carcinoma of gastrointestinal tract, 218 (Abst.)  
 growth and "heavy water," 1139 (Abst.)  
 metastatic, of tricuspid valve arising in case of malignant teratoma of testis, 749  
 multiple, 269  
 Tumor-bearing rats, histochemical studies of organs of, by microincineration method, 1293  
 Typhoid and paratyphoid immunization, agglutinin content of blood following, 415 (Abst.)  
 bacilli, isolation of, from water and sewage, 539 (Abst.)  
 carriers, serological diagnosis of, 442 (Abst.)  
 vaccination, agglutination, H & O following, and in an unselected group of individuals, 327 (Abst.)  
 Typhoid-like infection associated with an organism resembling *Bacillus proteus pseudovalerie* (De Assis), 1034
- U
- Ulcer, peptic, blood lipase in patients with, 1054  
 mechanism of pain in, studies of, 47  
 Uncinariasis, acute from massive infestation and its implications, 560 (Abst.)  
 Undernutrition, dietary treatment of, 1169  
 Undernutrition, dietary treatment of, 1169  
 1345 (Abst.)  
 laboratory diagnosis of, 1029 (E)  
 Urea clearance test in pregnancy, 677 (Abst.)  
 nitrogen in blood, direct nesslerization method for, where commercial urease is employed, 659  
 variations of, total nonprotein nitrogen and chloride concentration in blood following glucose ingestion, 471  
 Urease, commercial, is employed, direct nesslerization method for urea nitrogen in blood where, 659  
 Uremia, retention, blood cholesterol in chronic nephritis and, 906 (Abst.)  
 Uric acid, determinations of, rapid colorimetric method for multiple, 650  
 in human, bovine, and avian bloods, comparison of methods for determination of, 892  
 Urinary test as index of absorption of gall-bladder dye when given orally, 219 (Abst.)

- Urine and blood, chloral hydrate in, quantitative determination of, 1332  
 lactose and glucose in, practical method for simultaneous demonstration of, 211 (Abst.)  
 local anesthetics in, and in tissues, Diazo reaction for detection of certain, 1015  
 routine culture of, for tubercle bacilli, 675 (Abst.)  
 Voge bromine tests of, for pregnancy, five hundred and nineteen, 153  
 Urology, manual of, 333 (B. Rev.)

## V

- Vaccination, effect of, with B. C. G. on children from tuberculous families, 1347 (Abst.)  
 Vaccine and serum therapy, recent advances in, 1353 (B. Rev.)  
 Vaccines, comparison of relative values of intracutaneous skin test and of pathogen-selective culture in selecting bacteria for, from mixed cultures, 439 (Abst.)  
 Vacuum tube null indicator and glass electrode, determination of pH of normal and malignant tissues with, 1100  
 Vascular response to drainage of ascites, observations on, 918  
 Velocity factor in blood transfusion, 1206  
 Ventricular lesions, relationship between coronary blood supply to experimentally produced, and resulting electrocardiographic alterations, 1040  
 Vernes flocculation test in tuberculosis, 905 (Abst.)  
 Verrucous aortitis with special regard to aneurysm formation in children, 929  
 Vessel, combination condensing and receiving, 1116  
 Vitamin therapy in pulmonary tuberculosis, 966  
 Voge bromine tests of urine for pregnancy, five hundred and nineteen, 153
- W
- Wassermann and Kahn reactions upon spinal fluid in treated and untreated cases of paresis, comparison of, 546  
 test, study of Eagle antigens for, and flocculation test, 84  
 technic, a recommended, 621  
 Water and air balance during prolonged incubation, maintaining, 899  
 White blood cell dilution pipettes, calibration of, 95  
 Wright's blood stain, modified technic for bancrofti infection in man with an unusual history, 664

## X

- Xanthine diuretics, comparative study of certain, 248  
 X-ray, effect of salyrgan and, on rate of disappearance of thrombophlebitic edema, 243
